The lower margin of the tenth costal cartilage frequently corresponds to the most dependent part of the thoracic framework. Often, however, the eleventh costal cartilage descends $\frac{1}{4}$ to $\frac{1}{2}$ inch lower. Nevertheless, the tenth cartilage is selected in drawing the subcostal plane, for two chief reasons, namely, it is visible from the front as a rule, and it is comparatively fixed, whilst the eleventh, being a floating rib, is much more movable, is variable in length, and more difficult to locate.

**Contents of the Abdomen.**—The following structures are found within the abdominal cavity:—

1. The greater part of the *alimentary canal*, viz. stomach, small intestine, and large intestine.
2. *Digestive glands:* the liver and pancreas.
3. *Ductless glands:* the spleen and the two suprarenal bodies.
4. *Urinary apparatus:* the kidneys, ureters, bladder, and part of urethra.
5. The internal *generative organs* according to the sex.
6. *Blood* and *lymph vessels*, and *lymphatic glands.*
7. The abdominal portion of the cerebro-spinal and sympathetic *nervous systems.*
8. Certain *fœtal remains.*
9. The *peritoneum*—the serous membrane which lines the cavity, and is reflected over most of its contained viscera.

## THE PERITONEUM.

The arrangement of the peritoneum is so complicated, and its relations to the abdominal contents so intricate and detailed, that it will be expedient to postpone its complete description until the various organs, with their special peritoneal relations, have been separately considered. Nevertheless, it will be necessary to give here a general account of the disposition of the membrane, and to refer to the three varieties of folds which it forms in passing from organ to organ, or from these to the abdominal wall.

The **peritoneum** (tunica serosa) is the serous sac which lines the abdominal cavity and invests most of the abdominal viscera, to a greater or less degree. Like the pleuræ, the tunica vaginalis of the testicle, and other serous sacs, its walls are composed of a thin layer of fibrous tissue, containing numerous elastic fibres, and covered over on the side turned towards the cavity of the sac by flattened endothelial cells. Like them, too, the peritoneum in the male is a completely closed bag, but in the female this is not the case, for the abdominal end of each Fallopian tube opens into the sac, whilst the other end of that tube communicates with the interior of the uterus, and thus, indirectly, with the exterior. Normally the membrane secretes only sufficient moisture to lubricate its surface, otherwise the sac is perfectly empty, and its opposing walls lie in contact, thus practically obliterating its cavity.

The use of these lubricated and highly polished serous linings, found in the abdomen and certain other cavities, is to facilitate the movements of the contained viscera during any changes in size or form which they or their containing cavity may undergo. As a result of this arrangement, notwithstanding the tonic pressure of the abdominal wall on its contents, the stomach and intestines are free to move with the greatest ease and the least degree of friction, when any change takes place either in the organs themselves or in their surroundings.

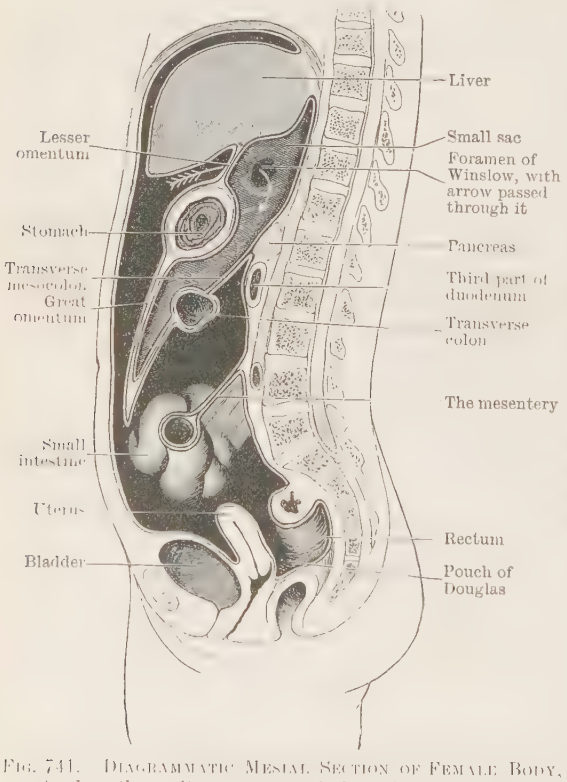

Fig. 741. Diagrammatic Mesial Section of Female Body, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the small sac is very darkly shaded; the peritoneum on section is shown as a white line; and a white arrow is passed through the foramen of Winslow from the great into the small sac.

The peritoneum is a thin glistening membrane, which may aptly be compared to a coat of varnish applied to the inner aspect of the abdominal walls, and to the surface of the contained viscera, except where these are directly applied to the walls or to one another. It forms throughout its entire extent a continuous and distinct sheet, but it is united so intimately to the viscera, and follows the irregularities of their walls so closely, that it appears at first sight to be a superficial layer of these walls, rather than a separate membrane. Outside the peritoneum lies the extra-peritoneal connective tissue—already described—which connects it more or less intimately to the fascial lining of the abdominal walls and to the abdominal viscera.

If we trace the peritoneum as a continuous layer, beginning in front, we find

that it lines the deep surface of the anterior abdominal wall, and is continued upwards to the under surface of the diaphragm (Fig. 741), the greater portion of which it covers. From the posterior part of the diaphragm it is reflected or carried forwards on to the upper surface of the liver, and then down over the stomach, intestines, and other abdominal viscera—clothing them all—to the pelvis. In like manner, when traced laterally from the anterior wall, the membrane will be found to line the sides of the cavity, and passing backwards to clothe the posterior abdominal wall, and the viscera lying upon it (Fig. 742, B). It should be pointed out that all the abdominal viscera are either directly fixed by connective tissue to the posterior abdominal wall, or suspended by blood-vessels from it. In the former case the peritoneum is reflected directly from the wall on to the viscera; in the latter it runs along the blood-vessels to reach the viscera, which it clothes, and then returns to the wall on the opposite sides of the vessels, which it thus encloses in a fold.

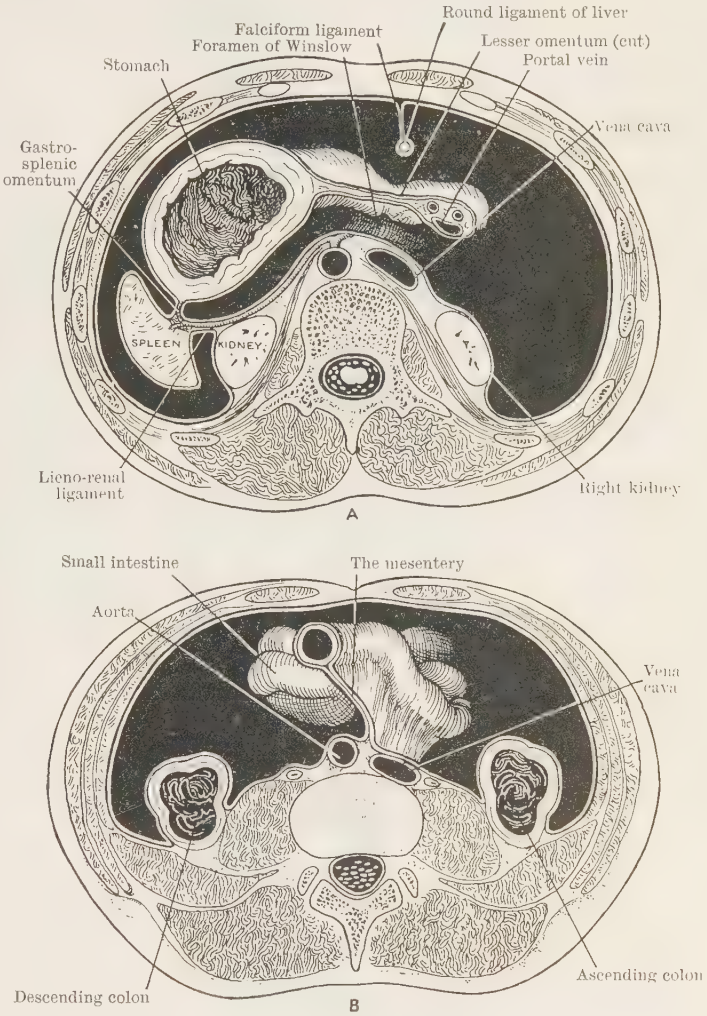

FIG. 742.—DIAGRAMMATIC TRANSVERSE SECTIONS OF ABDOMEN, to show the peritoneum on transverse tracing. A, at level of foramen of Winslow; B, lower down. In A note, one of the vasa brevia arteries passing to the stomach between the layers of the gastro-splenic omentum, and also the foramen of Winslow leading into the lesser sac which lies behind the stomach.

Whilst the main sac of the peritoneum lies in front of the various abdominal viscera, covering them over and dipping down between them, it should be mentioned that there is a special diverticulum derived from this "great sac," which turns in behind the stomach, and covers its posterior surface; this is known as the lesser or smaller sac, and it will be described in detail later on. The aperture through which one sac communicates with the other is termed the *foramen of Winslow.*

In passing from organ to organ, or from these to the abdominal wall, the peritoneum forms numerous folds, which are divided according to their connexions into three classes:—

(*a*) **Omenta** are folds of peritoneum which pass from the stomach to other abdominal organs. They are three in number, namely: (1) The *great* or *gastro-colic omentum,* which hangs down like an apron from the great curvature of the stomach, and passes to the transverse colon, connecting this latter, very loosely,

however, to the stomach; (2) the *lesser* or *gastro-hepatic omentum*, which extends from the lesser curvature of the stomach to the liver; and (3) the *gastro-splenic omentum*, which passes from the stomach to the spleen.

(*b*) **Mesenteries** are folds of peritoneum which unite portions of the intestine to the posterior abdominal wall, and convey to them their vessels and nerves. There are several mesenteries, *e.g.*, the *mesentery proper*, which connects the jejunum and ileum to the posterior abdominal wall, the *transverse mesocolon*, the *pelvic* (or "*sigmoid*") *mesocolon*, and occasionally others.

(*c*) **Ligaments** are peritoneal folds which pass between abdominal viscera other than portions of the digestive tube, or connect them to the abdominal wall. As examples of these may be mentioned most of the ligaments of the liver, the so-called "false ligaments" of the bladder, and the broad ligaments of the uterus.

This term is also applied to several small folds which connect portions of the intestinal tube to the parietes, but do not convey to them their vessels and nerves. The gastro-phrenic and phreno-colic ligaments are examples of these.

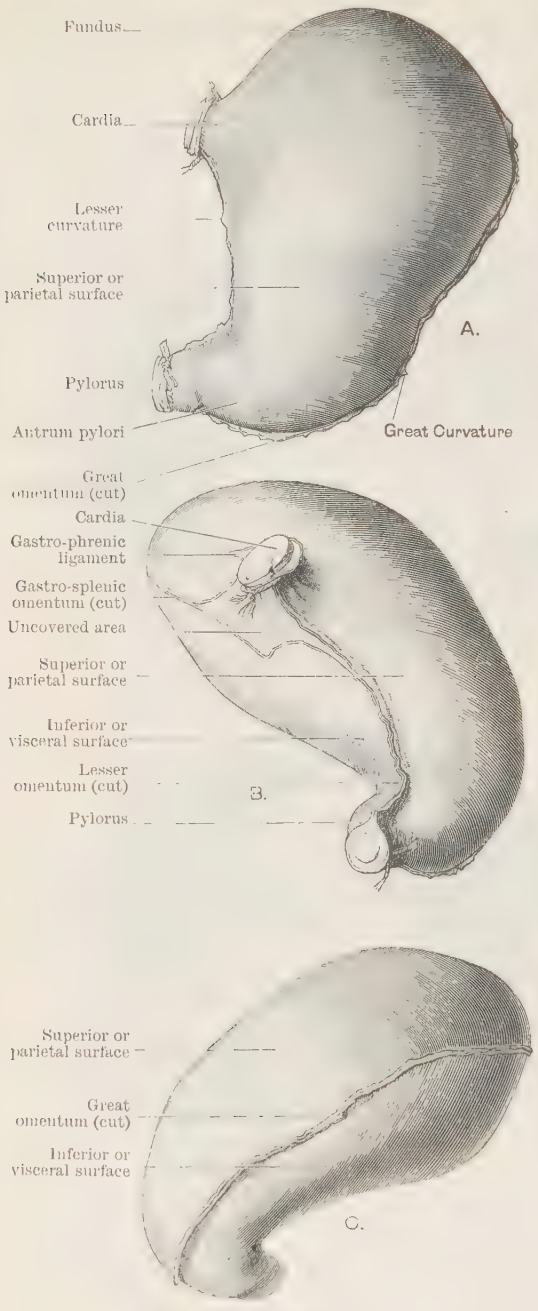

FIG. 743.—MODERATELY DISTENDED STOMACH, viewed, A, from front; B, from inner or right side; and C, from the outer or left side. (From photographs of the stomach shown in Figs. 739 and 744. The contents of the stomach were carefully removed through an artificial opening, and replaced with gelatine, the stomach remaining *in situ* throughout the operation. After the jelly hardened, its exact orientation was carefully noted, and pins indicating the vertical, horizontal, and transverse planes having been inserted, the organ was removed and photographed.)

## THE STOMACH.

The **stomach** (ventriculus) is the large dilatation found on the digestive tube immediately after it enters the abdomen (Figs. 743 and 744). It constitutes a receptacle in which the food accumulates after its passage through the œsophagus, and in it take place some of the earlier processes of digestion, resulting in the conversion of the food into a viscid soup-like mixture, known as chyme. The chyme as it is formed is allowed to escape intermittently through the pylorus, into the small intestine, where the digestive processes are continued.

Although the form of the stomach varies considerably under different conditions, in general it is of an irregularly pyriform shape, with a wide or cardiac end directed backwards and to the left, and a narrow pyloric end which runs to the right to join the duodenum. In addition to (*a*) its *two ends*, the stomach presents for examination the following parts: (*b*) *two*

*curvatures*, greater and lesser, separating (*c*) *two surfaces*, superior and inferior; and (*d*) *two orifices*, the œsophageal orifice or cardia, and the pyloric orifice or pylorus (Fig. 743).

**Position and Form of the Stomach.**—*When empty*, or nearly so, the stomach lies in the left hypochondrium and left part of the epigastrium, with its wide end or fundus directed backwards towards the diaphragm, its long axis lying almost in a horizontal plane, and its pyloric portion running to the right to join the duodenum. In this state the whole organ is narrow and attenuated, particularly the pyloric portion, which is contracted, and resembles a piece of thick-walled small intestine.

*When distended*, the organ assumes the form of an irregular pear, and both

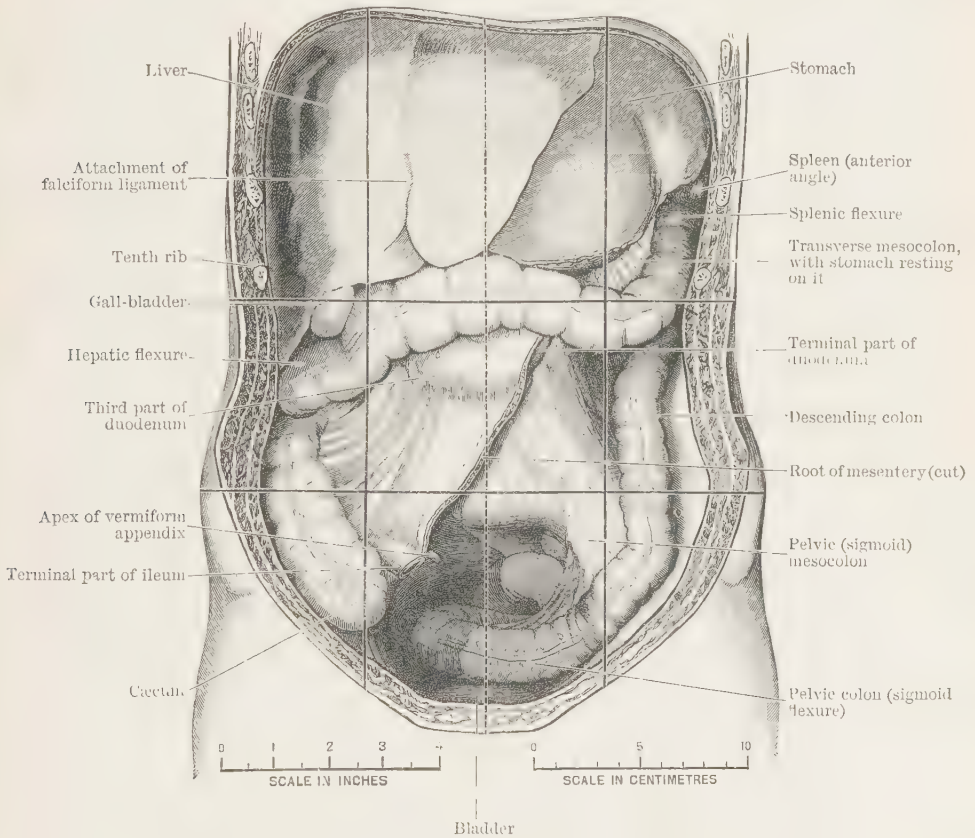

FIG. 744.—THE ABDOMINAL VISCERA AFTER THE REMOVAL OF THE JEJUNUM AND ILEUM (from a photograph of the same body as Fig. 739). The transverse colon is much more regular than usual. Both the liver and cæcum extend lower down than normal. The subdivisions of the abdominal cavity are indicated by dark lines.

the cardiac and pyloric portions become full and rounded (Fig. 743). It still lies within the hypochondriac and epigastric regions; but in extreme distension, or in exceptional cases, it may pass down below the subcostal plane and reach into the umbilical and left lumbar regions. As a result of the general increase in length which takes place during distension, the pylorus is moved a variable distance to the right beneath the quadrate lobe of the liver, and at the same time the long axis of the whole organ becomes much more oblique, running forwards, downwards, and to the right. Finally there is developed a special dilatation of the pyloric portion, known as the *antrum pylori*, which in extreme distension is carried so far to the right that it may even reach into the hypochondrium.

In brief, it may be said that the stomach when empty is contracted, not collapsed; that it assumes a narrow, attenuated shape, its cavity being practically obliterated, and its pyloric portion contracted to the size of small intestine; and in

addition, that its long axis lies in an almost horizontal plane. With distension there comes a general enlargement of the various diameters, an elongation of the whole organ, with a consequent passage of its pyloric portion to the right beneath the liver, the development of the antrum pylori, and an inclination of its axis from behind downwards and forwards, without any rotation.

**Natural Form of the Stomach.**—As seen in male bodies the viscera of which have been hardened by the intravascular injection of formalin, the *empty stomach*, as already stated, presents an attenuated or slender pear-shaped appearance, and is sharply bent on itself, particularly at the junction of the cardiac and pyloric portions. As a rule it is somewhat flattened from above downwards in its cardiac portion, but preserves in its whole length, more or less, an irregularly rounded or cylindrical form. Its long axis is directed, in the cardiac portion, from behind forwards and to the right with a slight inclination downwards; then it bends almost at a right angle, and in the pyloric portion runs to the right towards the pylorus.

Even in the empty condition, the cardiac portion retains, as a rule, an appearance of rotundity, and never assumes a completely collapsed and flattened form; although it sometimes is very much contracted, and approaches the tubular form of the pyloric portion.

The collapsed, flat-walled, and flaccid bag, often pictured as the empty stomach, does not represent its true condition during life, but is rather the result of post-mortem softening, relaxation, and pressure. The stomach, like the bladder, and like other hollow viscera with muscular walls, is not an inert bag, but an extensile living organ capable of expansion and contraction, which adapts the size of its cavity to the amount of its contents. When food enters, it expands, the expansion being proportionate to the amount of food that enters; and when the food passes away or is absorbed, it contracts, until its cavity is reduced to little more than a stellate lumen.

In the gradual passage of the stomach from the empty to the distended condition we may recognise three stages. *First stage.*—This commences with an enlargement of the fundus, and is followed by an expansion of the whole cardiac portion, which passes upwards and also to the left towards the diaphragm, displacing the coils of the transverse colon, which lie here when the stomach is empty. The pyloric portion for 3 or 4 inches still remains contracted and cylindrical. In this condition the stomach is frequently found after death. *Second stage.*—As distension goes on the lesser curvature opens out, the pyloric portion (with the exception of its last inch) expands, but its junction with the cardiac portion usually remains distinct, until distension is almost complete. *Third stage.*—A further general expansion of the whole stomach takes place; the diameters of both cardiac and pyloric portions, as well as the length of the organ, are increased; and the great curvature presses forwards against the anterior abdominal wall in front, where the restraining influence of the ribs is absent. The pyloric end for about 1 inch (2·5 cm.) from the pylorus remains narrow (constituting the pyloric canal of Jonnesco), but to the left of this it bulges forward, forming the antrum pylori, which is most distinct at the great curvature. By the increase of the organ in length the antrum is carried a considerable distance to the right beneath the liver—even further than the pylorus itself—so that the terminal part of the stomach is bent backwards and to the left, in order to reach the pylorus, which latter very rarely passes more than one and a half or two inches to the right of its normal position, namely, in the empty condition, within half-an-inch (12 mm.) of the middle line. Finally, as it fills, the stomach becomes gradually more oblique, so that in the distended state the long axis of the posterior two-thirds of the organ is directed forwards, downwards, and to the right, and forms an angle of about 40° to 45° with both the horizontal and sagittal planes (Fig. 743), whilst its anterior third is still more oblique.

There is, however (as pointed out by Jonnesco), no distinct rotation of the organ on its long axis—no turning of the great curvature more forwards, nor of the so-called anterior surface more upwards.

In the change from the distended to the empty state these stages are reversed; the whole stomach is contracted, or drawn in, from all directions towards the lesser curvature; this latter is bent upon itself to an acute angle, and the long axis of the organ, becoming less oblique, approaches the horizontal.

Although this description of the shape and direction of the stomach is at variance with the generally accepted accounts, it is based upon the examination of a considerable number of specially-hardened bodies, and has been found to apply so generally, that it is advanced here as the condition most frequently found in the male immediately after death, and as, in all probability, giving a near approximation to the conditions present during life. It must, however, be admitted that, in the female, as a result of tight lacing, the stomach is often found to assume an abnormal vertical position; but this condition is associated with displacement of other abdominal organs in the neighbourhood, and cannot be looked upon as normal.

[In the present edition it has been thought right to leave the above description of the stomach as it was originally written by Professor Birmingham. Subsequent investigation has served to show the accuracy of his views in so far as the various stomach forms which he describes are concerned, and the shape which he ascribes to the empty condition of the organ, and which he was the first to describe has been proved beyond dispute to be frequently met with in properly prepared subjects. The question, however, which is being at present discussed is whether this stomach-form, in which the cardiac part forms a more or less capacious sac, and the pyloric part is tubular and thick-walled, is not rather to be associated with a particular stage in the digestive act. From investigations on the cat by means of Röntgen rays, Cannon has shown that during

digestion the stomach becomes divided into a cardiac saccular reservoir in which no peristaltic movement can be detected, and a long tubular pyloric portion along which successive constriction waves are seen to be constantly passing. In the latter the food is triturated and mixed with the gastric juices, and when fully prepared it is squirted at irregular intervals through the pyloric orifice into the duodenum.—Ed.]

**Size and Capacity of the Stomach.**—Probably no organ in the body varies more in size within the limits of health than the stomach. Moreover, as its tissues change so rapidly after death, measurements made on softened and relaxed organs are not only worthless but quite misleading. Consequently it is difficult, perhaps impossible, to arrive at a correct estimate of its size and capacity.

The *length* of the stomach in the fully distended condition is about 10 to 11 inches (25 to 27·5 cm.), and its greatest *diameter* not more than 4 to 4½ inches (10 to 11·2 cm.); whilst its *capacity* in the average state rarely exceeds 40 ounces, or 1 quart.

The length has been estimated by different authorities at from 10 to 13½ inches (26 to 34 cm.); its diameter, from 3¼ to 6 inches (8 to 15 cm.); and its capacity from 1½ to 5 pints. The measurements of the capacity given by Dr. Sidney Martin are probably the most accurate: he states that the capacity varies between 9 and 59 oz., with an average of from 35 to 40, or a little over a litre.

The distance in a direct line from the cardiac to the pyloric orifice varies from 3 to 5 inches (7·5 to 12·5 cm.), and that from the cardia to the summit of the fundus from 2½ to 4 inches (6·2 to 10·0 cm.).

As regards the *weight*, I have found the average of twelve wet specimens freed from their omenta to be 4¾ oz. (135 grms.), with a maximum of 7 oz. (198·45 grms.) and a minimum of 3½ oz. (99·22 grms.). Glendenning gives the weight as 4½ ounces.

**Relations and Connexions of the Stomach.**—The relations will be much more readily understood if we briefly consider the disposition of the portion of the abdominal cavity in which the stomach lies, a portion which has such constant and definite surroundings that it perhaps merits the title of "stomach chamber."

The **stomach chamber** (Figs. 745 and 746) is a space in the upper and left portion of the abdominal cavity which is completely occupied by the stomach when that organ is distended, but into which the transverse colon also passes, doubling up over the stomach, when this latter is empty.

The chamber presents an arched roof, an irregularly sloping floor, and an anterior wall. The *roof* is formed partly by the visceral surface of the left lobe of the liver, and in the rest of its extent by the left cupola of the diaphragm, which arches gradually downwards behind and on the left to meet the floor.

The *floor* or "*stomach bed*" (Fig. 745) is a sloping shelf on which the under surface of the stomach rests, and by which it is supported. The bed is formed behind by the top of the left kidney (with its suprarenal capsule) and the gastric surface of the spleen; in front of this, by the wide upper surface of the pancreas; and more anteriorly still, by the transverse mesocolon running forwards above the small intestine, from the anterior edge of the pancreas to the colon (Fig. 745), which latter completes the floor anteriorly.

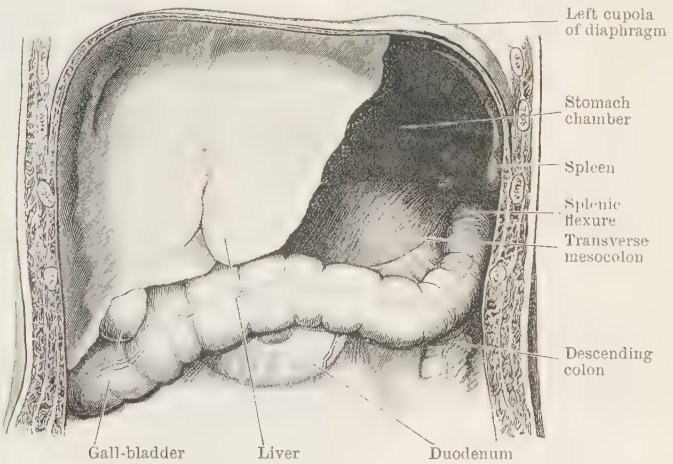

Fig. 745.—The Stomach Chamber and Stomach Bed.

From the same body as the preceding figure, after the stomach had been removed.

Finally, the *anterior wall* of the stomach chamber is formed by the abdominal wall, between the ribs on the left and the liver on the right side.

This chamber is completely filled by the stomach, when that organ is distended. When, on the other hand, the stomach is empty and contracted, it still rests on the floor, or stomach bed, but occupies only the lower portion of the chamber, whilst the rest of the space is filled by the transverse colon, which turns gradually upwards as the stomach retracts, and finally comes to lie both above and in front of that organ and immediately beneath the diaphragm—a fact to be remembered in clinical examinations of this region.

The **upper** (or parietal) **surface of the stomach** is more convex and more extensive than the lower. It lies, when the organ is distended, in contact with the roof and anterior wall of the stomach chamber, and thus comes into relation with the under surface of the left lobe of the liver on the right, the vault of the diaphragm on the left, and the anterior abdominal wall in front (Fig. 739). When the stomach is

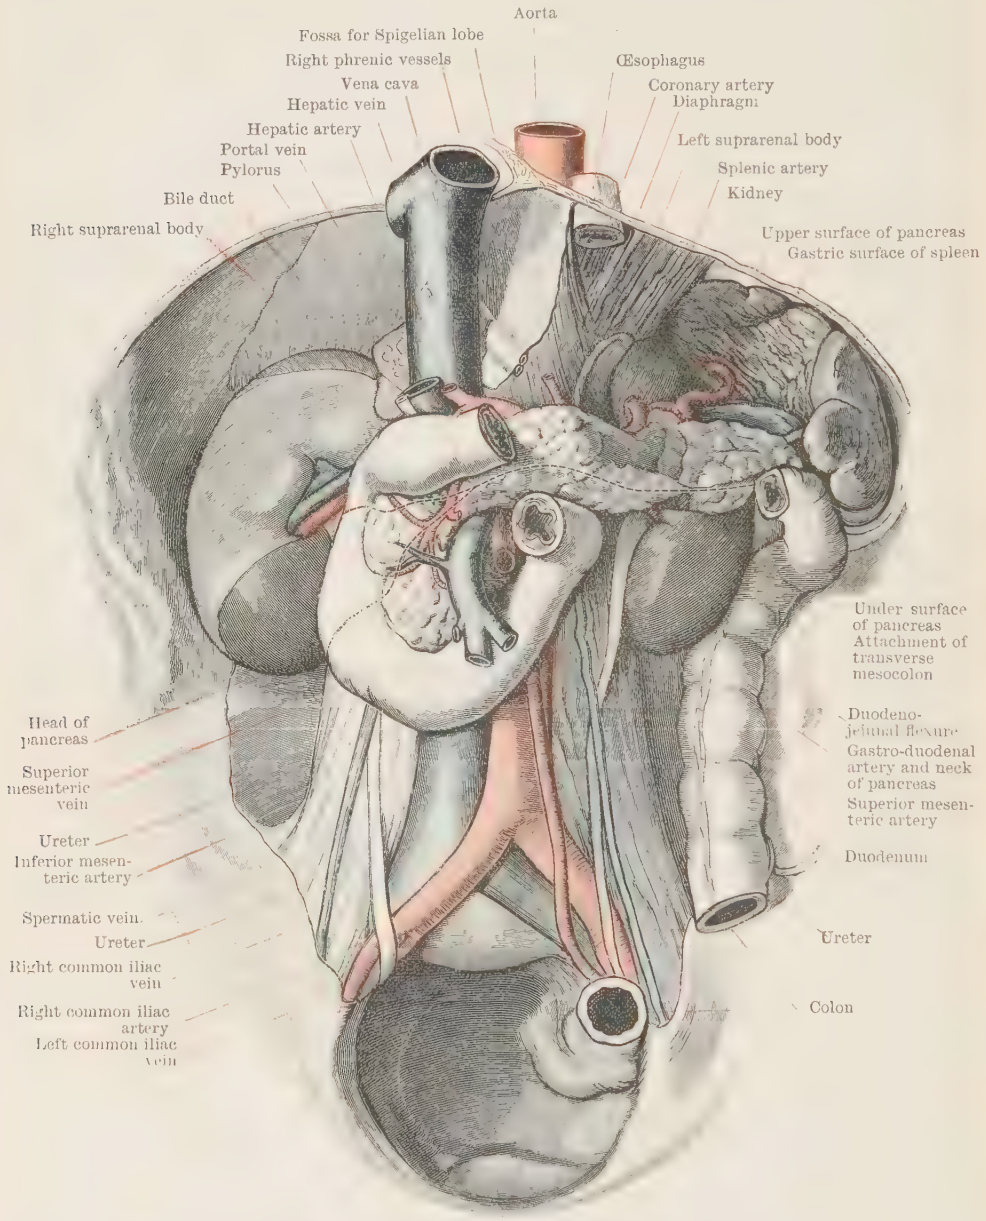

FIG. 746.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and also the fossa for the Spigelian lobe. In taking out the liver, the vena cava was left behind. The stomach bed is well shown. (From a body hardened by chromic acid injections.)

empty, on the other hand, the transverse colon, as just explained, doubles up over it, and separates this surface from the roof of the chamber.

The **lower** (or visceral) **surface**, more flattened than the upper, rests upon the stomach bed, and comes into relation with the following parts:—Behind, at the fundus, with the diaphragm and gastric surface of the spleen; in front of this with

the left kidney, the suprarenal, and the upper surface of the pancreas, and, more anteriorly still, with the transverse mesocolon and colon. From all of these the stomach is separated by the small sac of the peritoneum (the anterior layer of which clothes this surface), except below and to the left of the cardia, where the peritoneum is absent, over an irregularly triangular area (Fig. 743), and here the stomach lies in direct contact with the diaphragm (sometimes also with the top of the left kidney and suprarenal capsule).

It should be pointed out that the under surface of the stomach is separated from the duodeno-jejunal flexure and the beginning of the jejunum by the transverse mesocolon only. By cutting through this, the surgeon is enabled to bring the stomach and duodenum together in the operation of gastro-intestinal anastomosis.

The **cardiac end** or **fundus** (fundus ventriculi) is, in the distended condition, a large rounded cul-de-sac, which projects backwards and upwards against the left cupola of the diaphragm; opposite the œsophageal orifice it passes into the body of the stomach. Its surfaces are merely prolongations of the upper and lower surfaces of the organ, and accordingly its relations are similar.

Thus the upper surface lies against the left cupola of the diaphragm (and occasionally the left lobe of the liver, when this extends further than usual to the side); whilst the lower surface rests chiefly on the gastric surface of the spleen, and also on the left kidney.

The highest part of the fundus reaches to the level of a point on the chest wall about half-an-inch (12 mm.) internal to the apex point of the heart.

The **narrow** or **pyloric end**, when the stomach is empty, is contracted and cylindrical, and runs transversely to the right, lying as a rule beneath the left lobe of the liver. During distension it is carried to the right beneath the quadrate lobe, and its terminal part is there directed backwards in order to reach the duodenum. Even in this condition its last inch remains comparatively undistended.

The **lesser curvature** (curvatura ventriculi minor) is directed towards the liver, and corresponds to the line along which the lesser omentum is attached to the stomach, between the pyloric and œsophageal orifices (Fig. 743). It is connected to the liver by the lesser omentum, between the layers of which the gastric and pyloric vessels run along the curvature.

This curvature, when the stomach is empty, presents a sharp bend at the junction of the cardiac and pyloric portions, but when fully distended it forms an open curve except near its pyloric end, where it becomes convex, corresponding to the S-shaped form of this portion of the organ (see below). On viewing a distended stomach from the right side (Fig. 743, B), it will be observed that the line of the lesser curvature turns slightly on to the upper aspect in order to reach the cardia, which is situated rather on the upper surface than on the border of the stomach.

The **great curvature** (curvatura ventriculi major), which is usually over three times as long as the lesser curvature, corresponds to a line drawn from the cardia over the summit of the fundus (Fig. 743), and then along the line of attachment of the great omentum as far as the pylorus. In general, it is directed to the left and forwards, but at its beginning, near the cardia, it of course looks in the opposite direction. The great curvature corresponds in the greater part of its length to the attachment of the great omentum; and in close relation to it, but between the layers of the omentum, run the right and left gastro-epiploic vessels.

**Antrum Pylori.**—This is a prominence of the great curvature in the distended stomach, situated a short distance from the pylorus. When the stomach is distended, the pyloric portion, near its right extremity, becomes curved somewhat like the letter *S* placed horizontally. The first curve of the *S* is convex downwards and forwards, and this becoming more prominent with distension, forms a projection of the great curvature known as the antrum pylori. The terminal part of the *S* extends to the pylorus; it is about one inch (2·5 cm.) in length, and it appears never to become distended to any noticeable extent. This latter is the part described by Jonnesco as the pyloric canal.

The terms **cardiac** and **pyloric portions** are often employed to indicate the wider and narrower portions of the stomach respectively. The cardiac portion includes about two-thirds of the length of the whole organ; the pyloric portion the remaining third. Except in complete distension, the junction of the two is usually indicated by a slight constriction, and occasionally there is a thickening of the muscular fibres (apparently those of the oblique layer), corresponding in part to the constriction.

The **œsophageal orifice** or **cardia** is the aperture at which the gullet opens into the

stomach. It is situated at the upper end of the lesser curvature, to the right of the fundus, and nearer the upper than the lower surface of the stomach (Fig. 743, B). The cardia is very deeply placed, and lies about four inches behind the sternal end of the seventh left costal cartilage, at a point one inch from its junction with the sternum. Posteriorly it corresponds to the level of the eleventh dorsal vertebra.

Owing to the fixation of the œsophagus by its passage through the diaphragm, and the close connexion between the stomach and the diaphragm, near the cardia where the peritoneum is absent, this is the most fixed part of the whole organ. The object of this immobility is evidently to maintain a clear passage for the food entering the stomach. The orifice is oval rather than round, with its long axis very oblique; and although the presence of a valvular arrangement at the cardia has been advocated by several authorities, it is difficult to find satisfactory proof of its existence in hardened bodies. It seems more probable, on the whole, that no such arrangement naturally exists here. On the other hand, the muscular margins of the œsophageal opening in the diaphragm, and the circular fibres of the lower end of the œsophagus, which are particularly well developed, afford, by their simultaneous contraction, an effective means of closing the œsophagus immediately above the cardia, and thus of preventing regurgitation of the contents of the stomach.

The **pyloric orifice** or **pylorus** is the aperture through which the stomach communicates with the duodenum. It is marked on the surface by a slight constriction, most evident at the curvatures; and in the interior by a prominent thickening of the wall—the pyloric valve (valvula pylori)—produced by a special development of

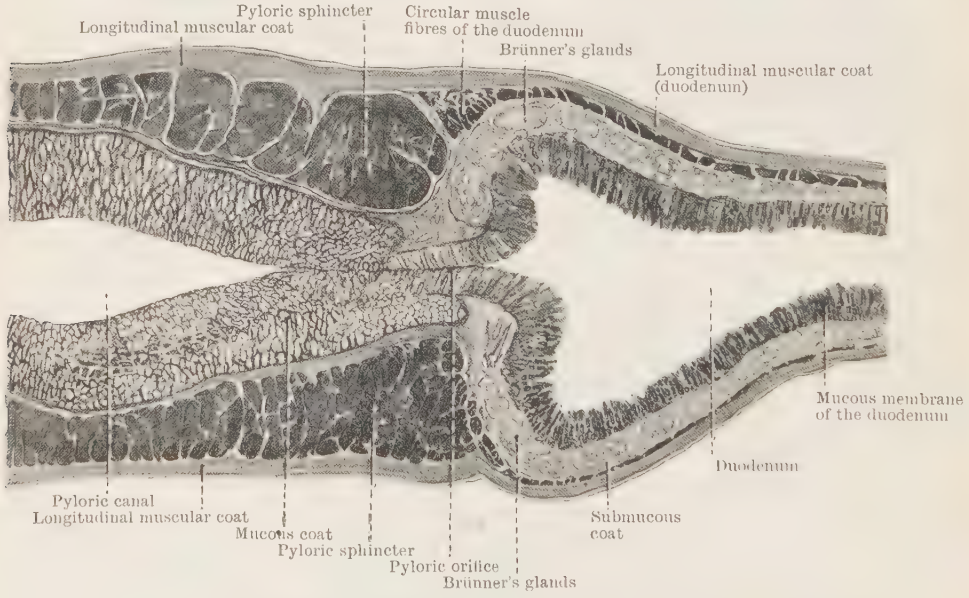

Fig. 747.—Longitudinal Section through the Pyloric Canal and Commencement of the Duodenum in a New-born Child. (From Stiles.)

the circular muscular fibres, known as the pyloric sphincter (musculus sphincter pylori). When examined post-mortem in the ordinary way, the aperture, viewed from the duodenal side, is somewhat oval in form, and closely resembles the external os uteri (Cunningham). When seen from the opposite side, it presents an irregular or stellate appearance, owing to the fact that the rugæ of the gastric mucous membrane are continued up to the orifice.

The pylorus rests on the neck of the pancreas below and behind, and is overlapped by the liver above and in front. Its average position can be marked on the surface of the body by the intersection of two lines; one drawn horizontally halfway between the top of the sternum and the pubic crest (Addison), the other drawn vertically a little way ($\frac{1}{2}$ inch, 12 mm.) to the right of the middle line.

During the earlier stages of gastric digestion the sphincter pylori is strongly contracted and the aperture firmly closed, but it opens intermittently to allow of the passage of properly digested portions of the food. As digestion advances the sphincter probably relaxes somewhat; but in hardened bodies a really patent pylorus is rarely or never found, which would seem to

indicate that the pylorus is normally closed, or nearly so, and that its opening is an active rather than a passive condition, as in the case of the anal canal.

As regards its size, the pylorus is stated to be about $\frac{1}{2}$ inch (12·5 mm.) in diameter, but there is no doubt that this represents neither its full size nor the calibre of the valve when at rest. Foreign bodies with a diameter of $\frac{3}{4}$ to 1 inch have been known to pass through the pylorus without giving rise to trouble, even in children. On the other hand, when at rest, with an empty stomach and duodenum, the aperture, as seen in formalin-hardened bodies, is practically closed, and presents a stellate or purse-mouth appearance, viewed from either aspect. In hardened bodies with distended stomach and duodenum, the aperture, which is somewhat oval, is practically closed, and from the duodenal side resembles, as Cunningham has shown, the external os uteri. But both in the empty and the distended condition of the stomach the pylorus seems to be rather a tubular narrowing, extending over at least $\frac{1}{2}$ to 1 inch of the canal, than a sudden constriction.

When the stomach is empty the pylorus is usually placed near (*i.e.* within $\frac{1}{2}$ inch, 12 mm. of) the middle line, beneath the left or sometimes the quadrate lobe of the liver, and at the level of the first lumbar vertebra, or the disc between this and the second lumbar. During distension it is pushed over beneath the quadrate lobe for a variable distance, but very rarely more than $1\frac{1}{2}$ or 2 inches to the right of the middle line; and its orifice, instead of looking towards the right, is then directed backwards, for, as already explained, the antrum in distension is carried to the right in front of the pylorus, or even beyond it.

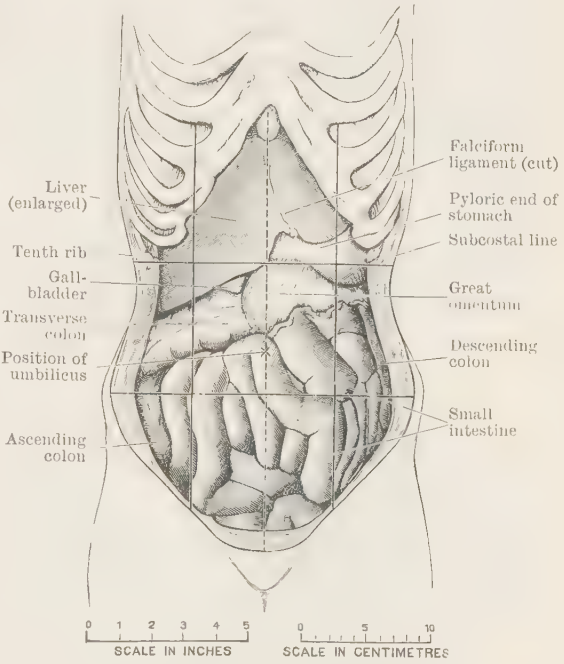

FIG. 748.—ABDOMEN OF FEMALE, SHOWING DISPLACEMENTS RESULTING FROM TIGHT LACING.

The liver is much enlarged, and extends on the left side to the ribs, where it was folded back on itself for over an inch. The pyloric end of the stomach and the beginning of the duodenum are quite superficial below the liver, and all the viscera are displaced downwards. (From a photograph of a body hardened by injections of formalin.)

**Peritoneal Relations.** — The stomach is almost completely covered by peritoneum—the anterior surface being clothed by the posterior layer of the great sac, and the posterior surface by the anterior layer of the small sac. From the lesser curvature the lesser omentum extends to the liver, whilst from the great curvature the great omentum passes down to the transverse colon. Higher up still, on the left, the continuation of the great omentum, namely, the gastro-splenic omentum, passes off (from the inferior surface, a little below the great curvature) to the spleen. Finally, a small peritoneal fold, known as the *gastro-phrenic ligament*, is found running from the stomach up to the diaphragm along the left side of the œsophagus.

A small, irregularly triangular, area (Fig. 744), about 2 inches wide and $1\frac{1}{2}$ inches from above downwards, during moderate distension of the stomach, on the inferior surface below and to the left of the cardia, is uncovered by peritoneum, and over it the organ is in direct contact with the diaphragm, occasionally also with the top of the left kidney and suprarenal. From the left angle of this "uncovered area" the attachment of the great omentum (gastro-splenic part) starts; and at the right angle the coronary artery passes on to the stomach.

**In the child at birth** the stomach is scarcely as large as a small hen-egg, and its capacity is about one ounce (28·3 grammes). In shape it corresponds pretty closely to that of the adult, and the fundus is well developed.

**In the female** (Fig. 748), as a result of tight lacing, the stomach is often displaced in position and distorted in shape, so that instead of running obliquely forwards, downwards, and to the right, it is placed nearly vertically along the left side of the vertebral column, in which direction it has a very considerable length. Its lower part bends rather suddenly, and runs upwards and to the right to join the pylorus, which is often placed quite superficially below the liver. As a result of the displacement, the left extremity of the

pancreas is pushed downwards from the horizontal until it almost assumes a vertical position. The narrowing and inversion of the lower margin of the thoracic framework at the same time constricts the stomach about its middle, and often leads to a bilocular condition.

**Hour-glass or Bilocular Stomach.**—This is a condition of the organ, by no means rare, in which the stomach is more or less completely separated into two divisions—a cardiac and a pyloric—the normal arrangement in certain rodents and other animals. As a rule the former division is the larger, but occasionally the two are nearly equal, or the pyloric portion may exceed the cardiac in size. Sometimes the condition is temporary, and the result of a vigorous contraction of the circular muscular fibres at the seat of constriction. In other cases it is permanent, and may be due to cicatricial contraction after gastric ulcer, or to some other pathological condition. The condition is more frequent in the female than the male, and is rarely found in the fœtus or child.

## Structure of the Stomach.

The stomach wall is composed of four coats—namely, from without inwards: (1) peritoneal, (2) muscular, (3) submucous, and (4) mucous (Fig. 749).

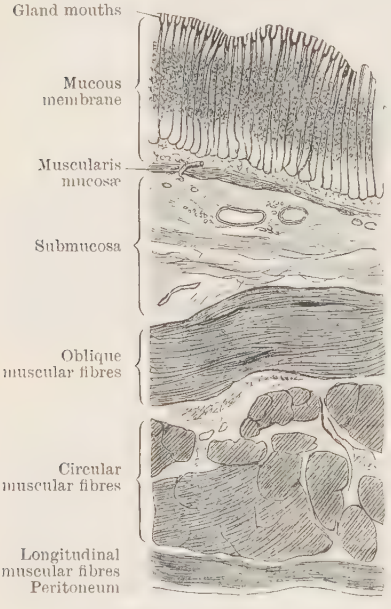

Fig. 749.—Section through Wall of Stomach, Cardiac Portion (slightly modified from Stöhr).

**Peritoneal** or **Serous Coat** (tunica serosa).—This coat is formed of the peritoneum, the relations of which to the stomach have already been described. It is closely attached to the subjacent muscular coat, except near the curvatures, where the connexion is more lax; and it confers on the stomach its smooth and glistening appearance.

**Muscular Coat.**—The muscular coat, which is composed of unstriped muscle, is thinnest in the fundus and body, much thicker in the pyloric portion, and very highly developed at the pylorus. It is made up of three incomplete layers—an external of longitudinal, a middle of circular, and an internal of oblique muscular fibres.

The *external layer* (stratum longitudinale) consists of longitudinal fibres, continuous with those of the œsophagus, on the one hand, and those of the duodenum on the other (Fig. 750, A). They are most easily demonstrated on the lesser curvature, where they can be traced down from the right side of the œsophagus. Over the great curvature and on the two surfaces they are present as an extremely thin and irregular sheet. Towards the pylorus the longitudinal fibres grow much thicker, and also much tougher and more closely united, but they do not take any part in the formation of the pyloric valve.

A specially-condensed band of these can be often made out both on the front and back at the antrum pylori, the form of which is said to be due to their presence. These bands are known as the pyloric ligaments (ligamenta pylori).

The *middle layer* (stratum circulare) is composed mainly of circular fibres, continuous with the more superficial of the circular fibres at the lower end of the œsophagus (Fig. 750, B). They do not commence as a series of circular bundles surrounding the fundus, as usually described. On the contrary, they begin as a set of U-shaped bundles which loop over the lesser curvature at the right of the cardia, and pass downwards and to the left on both surfaces. Further to the right these looped fibres are succeeded by circles which surround the organ completely. Traced towards the narrow end of the stomach, the circular bundles grow thicker, and at the pylorus they undergo a further increase, giving rise to the pyloric sphincter which surrounds the orifice as a thick muscular ring.

On the gastric side the pyloric sphincter passes gradually into the thick circular fibres of the pyloric portion of the stomach. On the opposite side it ceases abruptly, only its outer part being continued into the circular fibres of the duodenum (Fig. 751).

The *internal layer* (fibræ obliquæ) is composed of fibres which are arranged on the fundus and adjacent parts of the stomach, in much the same manner as those of the middle layer are on the body and pyloric portion of the organ (Fig. 750, C). Continuous above with the deeper circular fibres of the lower end of the œsophagus, they begin as

U-shaped bundles which loop over the stomach immediately to the left of the cardia, and run very obliquely downwards and to the right for a considerable distance on both surfaces of the organ. These looped fibres, as we pass to the left, gradually become less oblique, and finally form circles which surround the wide end of the stomach completely, even as far as the summit of the fundus. The oblique fibres can be most readily shown by removing the circular fibres on either surface below the cardia. When traced towards the right, they will be found to terminate by turning down and joining the fibres of the circular layer.

**Submucous Coat** (tela submucosa).—The submucous coat is a layer of strong but loose connective tissue, which lies between, and unites the muscular and mucous coats (Fig. 749). It is more loosely attached to the former and more closely to the latter coat, and it forms a bed in which the vessels and nerves break up before entering the mucous membrane.

**Mucous Coat** (tunica mucosa).—If examined in the fresh state soon after death, the mucous coat is of a reddish-gray colour and of moderate consistence. When examined some time after death, the colour turns to a darker gray, and the whole membrane becomes softer and more pulpy. It is thicker (over 2 mm.) and firmer in the pyloric than in the cardiac portion, and is thinnest at the fundus, where it often shows signs of post-mortem digestion. When the stomach is empty all three outer coats, which are extensile, contract; whilst the inextensile mucous coat, as a result of its want of elasticity, is thrown into numerous prominent folds or *rugæ*, which project into the interior and, as it were, occupy the cavity of the contracted organ. These are, in general, longitudinal in direction, with numerous cross branches, and they are largest and most numerous along the great curvature. They disappear when the stomach is distended.

FIG. 750.—THE THREE LAYERS OF THE MUSCULAR COAT OF THE STOMACH. A, Outer or longitudinal layer; B, Middle or circular layer; C, Internal or oblique layer. *a*, Longitudinal fibres of œsophagus; *b*, Superficial circular fibres of œsophagus passing into circular fibres of stomach in B: *c*, Deep circular fibres of œsophagus passing into oblique fibres of stomach in C; *d*, Oblique fibres forming rings at the fundus; *e*, Submucosa.

When the surface of the mucous coat is examined in a *fresh* stomach, it is seen to be marked out into a number of small, slightly elevated, polygonal areas (areæ gastricæ) by numerous linear depressions; the mucous membrane is consequently said to be *mammillated* (Fig. 752, A). These little areas, which measure from 1 to 6 mm. in diameter, are beset with numerous small pits (foveolæ gastricæ, about ·2 mm. wide), which are the mouths of the gastric glands, and they are so closely placed that the amount of surface separating them is reduced (particularly in the pyloric portion, where the gland mouths are widest) to a series of elevated ridges (plicæ villosæ) resembling villi on section. Although the gland mouths cannot be seen with the naked eye, a very slight magnification is sufficient to show them clearly; it is also possible to see the gland tubes leading off from the bottom of each (Fig. 752, B).

**Blood-vessels.**—The **arteries** of the stomach are all derived ultimately from the cœliac axis. The *coronary* arises from this trunk direct. Having reached the lesser curvature and given off an œsophageal branch, it divides into two large branches, which run, one on each side, along this curvature, and join below with two similarly disposed arteries derived from the *pyloric* branch of the hepatic. From the two arches thus formed, four or five large branches pass to each surface of the stomach, and soon pierce the muscular coat. Along the great curvature several smaller branches reach the stomach from the *right and left gastro-epiploic arteries*, which are branches respectively of the gastro-duodenal and the splenic, and run in the great omentum close to its attachment to the stomach. Finally, four or five *vasa brevia*, branches of the splenic, are distributed to the fundus of the stomach, which they reach by passing forwards between the layers of the gastro-splenic omentum. At first the arteries lie beneath the peritoneum; very soon, however, they pierce the muscular coat, which they supply, and reaching the submucosa, break up to form a close network of vessels. From these arise numerous small branches, which enter the mucous membrane and form capillary plexuses around the glands as far as the surface.

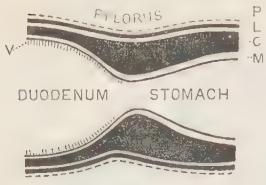

FIG. 751.—DIAGRAM TO SHOW FORMATION OF PYLORUS. P, Peritoneum; L, Longitudinal layer of muscular fibres; C, Circular layer; M, Mucous membrane; V, Villi. It will be seen that the pyloric narrowing is due practically entirely to a gradual thickening of the circular muscular fibres, which stops abruptly at the pyloric orifice.

The **veins** begin in the capillary plexuses around the glands; uniting, they form a network in the submucosa, from which arise branches that pierce the muscular coat, and finally end in the following veins: the *right gastro-epiploic*, which joins the superior mesenteric; the *left gastro-epiploic*, and four or five veins corresponding to the *vasa brevia arteries*, which join the splenic; the *coronary* or *gastric vein*, which runs along the lesser curvature towards the cardia, receives an œsophageal branch, and then turns down and runs beside the coronary artery to join the portal trunk; and the *pyloric vein*, corresponding to the same named artery, which also joins the portal. These veins contain numerous valves, which, though competent to prevent the return of blood in the child, are rarely so in the adult.

The **lymphatics** arise in the mucous membrane around the gastric glands; they then join a plexus of valved vessels in the submucosa, from which the chief trunks pass with the blood-vessels to the curvatures, being joined on the way by the efferent vessels of a subperitoneal lymphatic plexus. They are connected with the superior gastric glands along the lesser curvatures, the inferior gastric glands along the great curvature, and the splenic glands, which they reach with the vasa brevia. Finally, the efferent vessels of all these join the cœliac glands.

The **nerves** are derived from the two *pneumogastrics* and from the *solar plexus* of the sympathetic. The pneumogastric nerves pass down through the diaphragm with the œsophagus, the left lying on its front, the right on its back; in this way they reach the upper and lower surfaces of the stomach respectively. Here they unite with the sympathetic fibres from the cœliac plexus (an offshoot of the solar plexus), which pass to the stomach with the branches of the cœliac axis. The nerve fibres, which are chiefly non-medullated, form two gangliated plexuses, those of Auerbach and Meissner, in the muscular and submucous coats respectively.

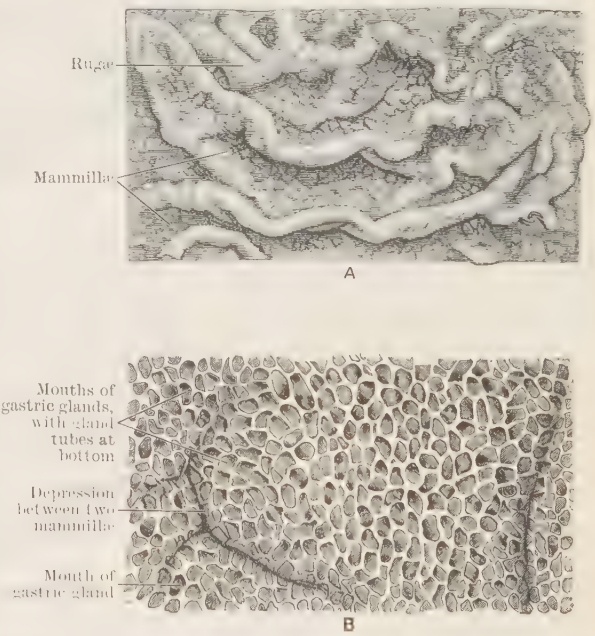

FIG. 752.—THE MUCOUS MEMBRANE OF STOMACH. A, Natural size; B, Magnified 25 diameters. In A the rugæ and the mammillated surface are shown. In B the gland mouths (foveolæ gastricæ), with the gland tubes leading off from some of them, and the ridges separating the mouths (plicæ villosæ) are seen.

The development of the stomach is described with that of the intestines on p. 1105.

## INTESTINES.

As the coats of the remaining portions of the digestive tube agree in many particulars, it will be convenient to describe the general structure of the intestines

here. Subsequently, any peculiarities of structure in particular regions will be described with the corresponding division of the tube.

## Structure of the Intestines.

The wall of the intestines, like that of the stomach, is made up of four coats, which are named from without inwards—serous or peritoneal, muscular, submucous, and mucous (Figs. 753 and 754).

1. **Serous Coat** (tunica serosa).—This is formed of peritoneum, and confers on the intestines their smooth and glossy appearance. It varies in the extent to which it clothes the different divisions of the tube, giving the duodenum, the ascending, descending, and

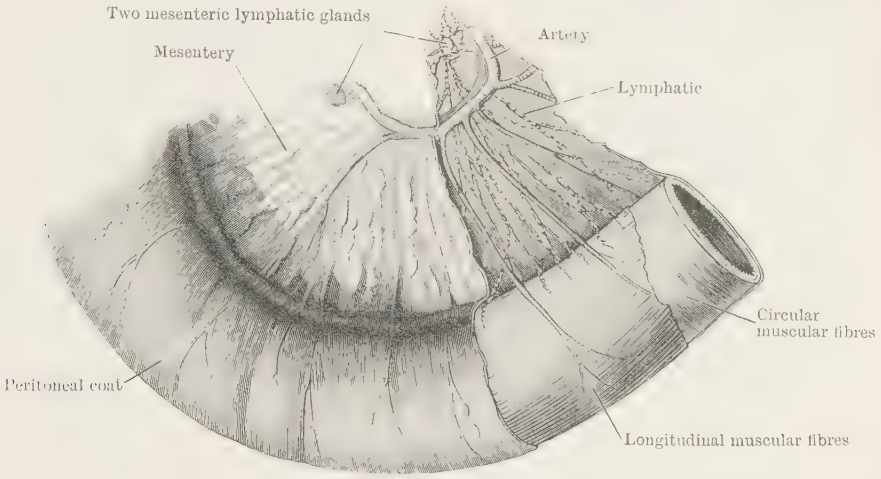

Fig. 753.—A Portion of Small Intestine, with Mesentery and Vessels. The peritoneal coat has been removed from the right half, and the two layers of the muscular coat exposed.

iliac colons, and the rectum only a partial covering; whilst it clothes the jejunum and ileum, the cæcum, the transverse and the pelvic colons completely. The detailed arrangement of this coat will be given with the description of each division of the intestinal tube.

2. **Muscular Coat** (tunica muscularis).—This consists of unstriped muscle arranged in two layers—an outer, in which the fibres run longitudinally, and an inner, in which they are circularly disposed. The muscular coat is thicker in the duodenum than in any other part of the small intestine, and it gradually diminishes in thickness until the end of the ileum is reached. On the other hand, in the large intestine, it is thickest in the rectum and thinner towards the beginning of the colon.

The **longitudinal layer** (stratum longitudinale) of this coat is much thinner than the underlying circular layer. In the small intestines it forms a complete sheet, continuous all round the gut (Fig. 753), but thickest at its free margin; whilst in the large intestine it is divided up into three longitudinal bands (Fig. 762), known as the *tæniæ coli*, which will be more fully described in connexion with the colon.

The **circular layer** (stratum circulare), much thicker than the longitudinal layer, is composed of bundles of muscular fibres arranged circularly round the tube (Fig. 753), and forming in all parts a continuous sheet. Unlike the longitudinal fibres, those of the circular layer take part in the formation of the pyloric and ileo-cæcal valves.

3. **Submucous Coat** (tela submucosa).—This is a loose but strong layer of areolar tissue connecting the muscular and mucous coats, on which chiefly depends the strength of the intestinal wall. In addition to forming a bed in which the vessels break up before entering the mucous coat, it contains the glands of Brunner in the duodenum (Fig. 754), and in both small and large intestine the bases of the solitary glands lie in it (Fig. 754).

4. **Mucous Coat** (tunica mucosa).—The mucous membrane constitutes the inner coat of the intestine, on which its digestive functions depend. It is everywhere composed (Fig. 754) of the following parts:—(1) A layer of striated, columnar, epithelial cells resting on (2) a basement membrane. Outside this lies (3) a layer of retiform tissue, containing a considerable number of scattered lymphoid cells. This layer is limited towards the submucosa by (4) an extremely thin sheet of unstriped muscle, the

**muscularis mucosæ**, which is not visible to the naked eye. The mucous membrane is very vascular, particularly in the small intestine. It is thicker in the duodenum than in the jejunum, and thicker in this latter than in the ileum.

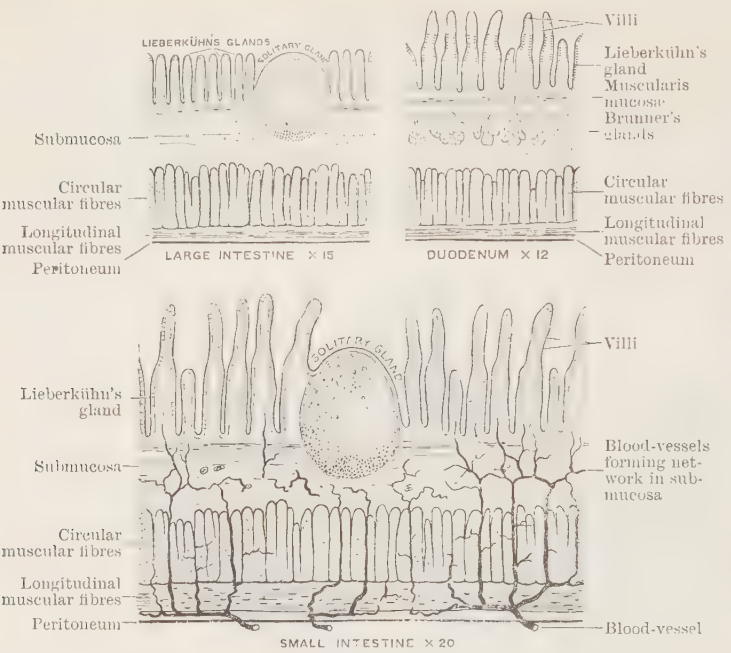

FIG. 754.—DIAGRAM to show the structure of the small and large intestine and the duodenum.

Throughout both the small and large intestines the substance of the mucous membrane is closely beset with innumerable small (microscopic) tubular glands, known as the **glands** or **follicles of Lieberkühn** (glandulæ intestinales). In shape they are minute straight tubes—like diminutive test-tubes—with their mouths opening on the surface, their closed ends lying in the deeper part of the mucous coat, and their cavities lined by columnar epithelium. They open on the surface between the villi of the small intestine, and are present also on the valvulæ conniventes. In the large gut their orifices are found all over the surface of the mucous membrane.

Certain special developments of the mucous coat, found in particular regions of the intestinal tube, must next be considered: these are the (1) villi; (2) valvulæ conniventes; (3) solitary glands; and (4) agminated glands, or Peyer's patches.

**Villi** (villi intestinales).—If the mucous membrane of any part of the small intestine be examined, it is seen to present a soft, velvety, or fleecy appearance (Fig. 755, B); this is due to the presence of an enormous number of minute processes, known as villi, which cover its surface.

Villi are minute cylindrical or finger-like projections of the mucous membrane (Fig. 754), about $\frac{1}{30}$th or $\frac{1}{40}$th of an inch (1·2 to 1·6 mm.) in height, and barely visible to the naked eye, which are closely set all over the surface of the mucous membrane of the small intestine. Beginning at the edge of the pyloric valve, they are said to be broader but shorter in the duodenum, and to grow narrower as they are followed down through the intestine to the ileo-cæcal valve, at the edge of which they cease. They are found, not only on the general surface of the mucous membrane, but also upon the valvulæ conniventes, and, while they are not present over the solitary glands, they are found in the intervals between the individual nodules of the Peyer's patches.

They are connected with the absorption of the products of digestion which takes place in the small intestine.

**Valvulæ Conniventes** (plicæ circulares).—When the intestine is empty and contracted, its mucous membrane may in places be thrown into effaceable folds or rugæ, which disappear on distension. But in addition to these, there are found in certain portions of the small intestine a series of large, permanent folds, which are not effaceable; these are known as valvulæ conniventes (Fig. 755). They are usually more or less crescentic in shape, and resemble a series of closely-placed shelves running transversely around the gut. They rarely form more than two-thirds of a circle; sometimes, however, they present a circular or even a spiral arrangement, the spiral extending little more than once round the tube, as a rule.

Occasionally they bifurcate at one or both ends; sometimes, too, short irregularly directed branches pass off from them. They are usually about 2 to 3 inches (5 to 7·5 cm.) in length, and their breadth, that is their projection into the cavity, may be as much as $\frac{1}{3}$rd of an inch (8 mm.), whilst in thickness, as seen when cut across, they measure about $\frac{1}{8}$th inch (3 mm.).

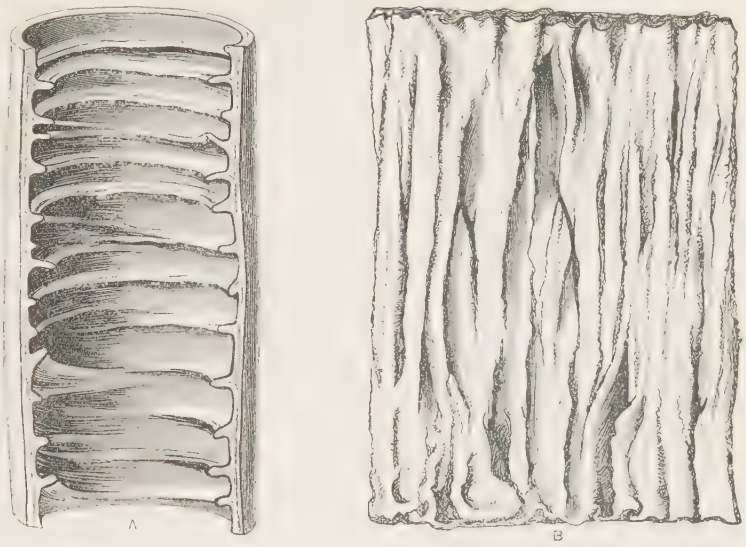

Fig. 755.—Valvulæ Conniventes (natural size).

A, as seen in a bit of jejunum which has been filled with alcohol and hardened; B, a portion of fresh intestine spread out under water.

They are composed of two layers of mucous membrane, placed back to back, with a little submucosa between, to bind the two together, and are covered with villi and Lieberkühn's glands. Their use is to increase the amount of surface available for secretion and absorption.

Valvulæ conniventes are not found in the upper part of the duodenum. They begin at a distance varying from 1 to 2 inches (2·5 to 5 cm.) from the pylorus. At first they are small, irregular, and scattered; but they grow gradually larger as we pass down, and when the opening of the bile-duct is reached (4 inches from the pylorus) they have become distinct and prominent. In the rest of the duodenum, and in the upper half of the jejunum, they are highly developed, being large, broad, and closely set. In the lower half of the jejunum they become gradually smaller and fewer. Passing down into the ileum, they become still smaller and more irregular, and, as a rule, they practically cease a little below the middle of the ileum.

The mucous membrane covering the folds possesses villi, solitary glands, and Lieberkühn's glands, like the mucous membrane of the general surface between the valves.

Often patches of valvulæ conniventes, much reduced in size, can be traced to within a short distance of the ileo-cæcal valve. According to Sappey, Luschka, and others, they usually reach to within two or three feet of the end of the ileum.

**Solitary Glands** (noduli lymphatici solitarii).—These are minute nodules of lymphoid tissue, opaque and of a whitish colour, found projecting on the surface of the mucous membrane throughout the whole length of both the small and large intestines.

Isolated lymphoid cells are found in abundance scattered through the connective tissue layer of the intestinal mucous membrane generally; in places these cells are gathered together to form little nodules, supported by a framework of retiform tissue, and surrounded by a lymphatic space which communicates below with the lymphatics of the submucosa. Such a collection of lymphoid cells constitutes a solitary gland. They are usually of a rounded or oval shape (Fig. 754), the wide end resting in the submucosa, the nodule itself piercing the muscularis mucosæ, and the narrow end projecting slightly above the surface of the mucous membrane. In size they vary from $\frac{1}{40}$th to $\frac{1}{8}$th of an inch (·6 to 3·0 mm.), but their average bulk is about that of a small grain of sago, to which they bear some resemblance.

As already mentioned, they are present throughout the small and large intestines, being particularly abundant in the vermiform appendix and cæcum. In

the small intestine they are found on the valvulæ conniventes, as well as upon the general surface of the mucous membrane between them.

**Peyer's Patches**, or **Agminated Glands** (noduli lymphatici aggregati, tonsillæ intestinales).—A Peyer's patch consists of a large number of lymphoid nodules grouped closely together so as to form a slightly elevated area, usually of an oblong form, on the surface of the mucous membrane (Fig. 756). In length they vary from half an inch (12 mm.) or less to three or four inches (100 mm.), and in width they commonly measure from a third to half an inch (8 to 12 mm.). Their number is variable, but in the average condition about 30 or 40 are found. They are best marked in young subjects, where they form considerable elevations above the general surface, and may be as many as 45 in number. After middle life they atrophy, and in old age, although usually to be found, they are indistinct, occasionally being marked by little more than a dark discoloration of the mucous membrane. They are invariably situated along the free surface of the intestine opposite the line of mesenteric attachment, with their long axis corresponding to that of the bowel. Consequently, in order to display them, the tube must be slit up along its attached or mesenteric border.

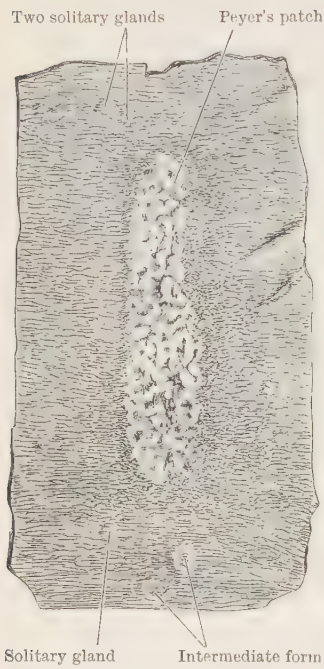

FIG. 756.—PEYER'S PATCH AND SOLITARY GLANDS, from intestine of child two years old (natural size).

Near the lower border are seen a few small patches made up of two or three lymphatic nodules; they are marked "intermediate form."

Peyer's patches are entirely confined to the small intestine, being largest and most numerous in the ileum, particularly in its lower part, where they usually assume an oblong shape; in the lower half of the jejunum they are small, circular, and few in number; in its upper part they are rare; and, although their presence has been noted in the lower portion of the duodenum, they may be said to be as a general rule absent from this division of the intestine.

The valvulæ conniventes stop at the margins of Peyer's patches, and are not continued across them; but villi are found on the surface of the patches, in the intervals between the lymphoid nodules.

The chief bowel lesion in typhoid fever is found in Peyer's patches and the solitary glands.

When the surface of a Peyer's patch from a child's intestine (in which these structures are particularly well developed) is carefully examined, it is seen to be made up, not of a series of separate, rounded nodules grouped together, but rather of a number of wavy, irregular, and branching ridges connected with one another by cross branches (Fig. 756), the whole recalling in miniature the appearance of a raised map of a very mountainous district in which the chief chains run irregular courses, and are joined to one another by connecting ridges.

Small patches, intermediate in form between solitary glands and Peyer's patches, and consisting of two or three lymphoid nodules, are also usually present.

## THE SMALL INTESTINE.

The **small intestine** is the portion of the digestive tube which is placed between the stomach and the beginning of the large intestine. It commences at the pylorus, where it is continuous with the stomach, and ends at the ileo-cæcal valve by joining the large intestine. It occupies the greater portion of the abdominal cavity below the liver and stomach (Fig. 740), and is found in the umbilical, hypogastric, and both lumbar regions; also, but to a less extent, in the other regions of the abdomen, and in the pelvic cavity.

In *length*, the small intestine usually measures over 20 feet. According to Treves, it is 22½ ft. in the male, 23 in the female, whilst Jonnesco gives the average length at 24 ft. 7 ins., or 7½ metres. In form it is cylindrical, with a *diameter* varying from nearly two inches (47 mm.) in the duodenum to a little over an inch (27 mm.) at the end of the ileum; there is thus a gradual diminution in its size from the pylorus to the ileo-cæcal valve.

This portion of the digestive tube is divided more or less arbitrarily into three parts (Fig. 705)—namely, the **duodenum**, constituting the first eleven inches, distinctly marked off from the rest by its fixation and the absence of a mesentery; the **jejunum**, which comprises the upper two-fifths, and the **ileum**, the lower three-fifths of the remainder. The two latter parts pass imperceptibly into one another, and the line of division drawn between them is entirely artificial; however, if typical parts of the two—namely, the beginning of the jejunum and the end of the ileum—be selected, they differ so much in size and in the appearance presented by their lining mucous membrane, that they can be distinguished from one another without difficulty.

Both the jejunum and ileum are irregularly disposed in the form of crowded loops or coils (Fig. 739) which are connected to the posterior abdominal wall by a great fan-shaped fold of peritoneum, containing their vessels and nerves, and known as the **mesentery**. This is of such a length that the coils are able to move about freely in the abdominal cavity, and consequently the position occupied by any portion of the tube, with the exception of the beginning of the jejunum and the ending of the ileum, can never be stated with certainty. Nevertheless, it may be said that, in general, the jejunum occupies the upper and left portions of the cavity below the stomach, the ileum the lower and right divisions, its terminal part almost always lying in the pelvis, just before it joins the large gut.

The small intestine is relatively longer in the child than in the adult; at birth it is to the total height of the child as 7 to 1, whilst in the adult the proportion is as 4 to 1. Notwithstanding Treves' results, it is generally held that the small gut is relatively longer in the male than the female.

It should perhaps be added that in formalin-hardened bodies the small bowel rarely measures more than 12 or 13 feet in length. Similarly its diameter is often reduced in places to $\frac{1}{2}$ or $\frac{3}{4}$ inch (12·5 to 18·7 mm.), although the greater part of the gut may retain its usual width: these narrow parts have apparently been fixed in a state of contraction.

## THE DUODENUM.

The **duodenum**, the portion of the digestive tube which immediately succeeds the stomach, is the first part of the small intestine, and differs from the rest of that tube in having no mesentery, and also in being closely fixed to the posterior abdominal wall—conditions which are evidently associated with its relation to the bile and pancreatic ducts, both of which open into its cavity.

**Shape and Divisions.**—The duodenum begins at the pylorus, about the level of the first lumbar vertebra, and ends, after a somewhat C-shaped course, at the left side of the first or second lumbar vertebra (Fig. 757). It is generally described as being made up of three parts, namely:—(1) The **first** or **superior portion**, which begins at the pylorus, passes backwards and to the right beneath the liver, and ends at the neck of the gall-bladder, by turning down and joining (2) the **second** or **descending portion**. This begins at the neck of the gall-bladder, runs down behind the transverse colon (Fig. 758), and ends opposite the third or fourth lumbar vertebra by turning to the left, and passing into (3) the **third** or **inferior portion**. This at first runs more or less transversely to the left, across the vena cava, and then ascends, in front of the aorta, as far as the under surface of the pancreas, where, at the level of the first or second lumbar vertebra, it bends abruptly forwards, forming the **duodeno-jejunal flexure** (Fig. 757), and passes into the jejunum.

Taking the whole of the duodenum together, it forms an irregularly C-shaped curve, with the opening of the C directed upwards and to the left, and the ends reaching to within about two inches of one another. Within the concavity of the curve the head of the pancreas is placed.

The incomplete ring which the duodenum makes does not all lie in the same plane; for, whilst its greater part is placed in a transverse-vertical plane, the middle portion bends strongly backwards, round the right side of the vena cava, and lies almost in a sagittal plane (Fig. 757).

**Position and Size.**—As a rule, a little more than half of the duodenum lies in the epigastrium, the remainder, namely, about the lower third of the descending

portion and the adjoining two-thirds of the inferior or third portion, are placed in the umbilical region. With the exception of the terminal ascending portion of the third part, the whole of the duodenum lies to the right of the middle line.

Its length is usually about 11 inches (27·5 cm.), its first portion being the shortest and its third portion the longest. Its diameter varies considerably, and may be

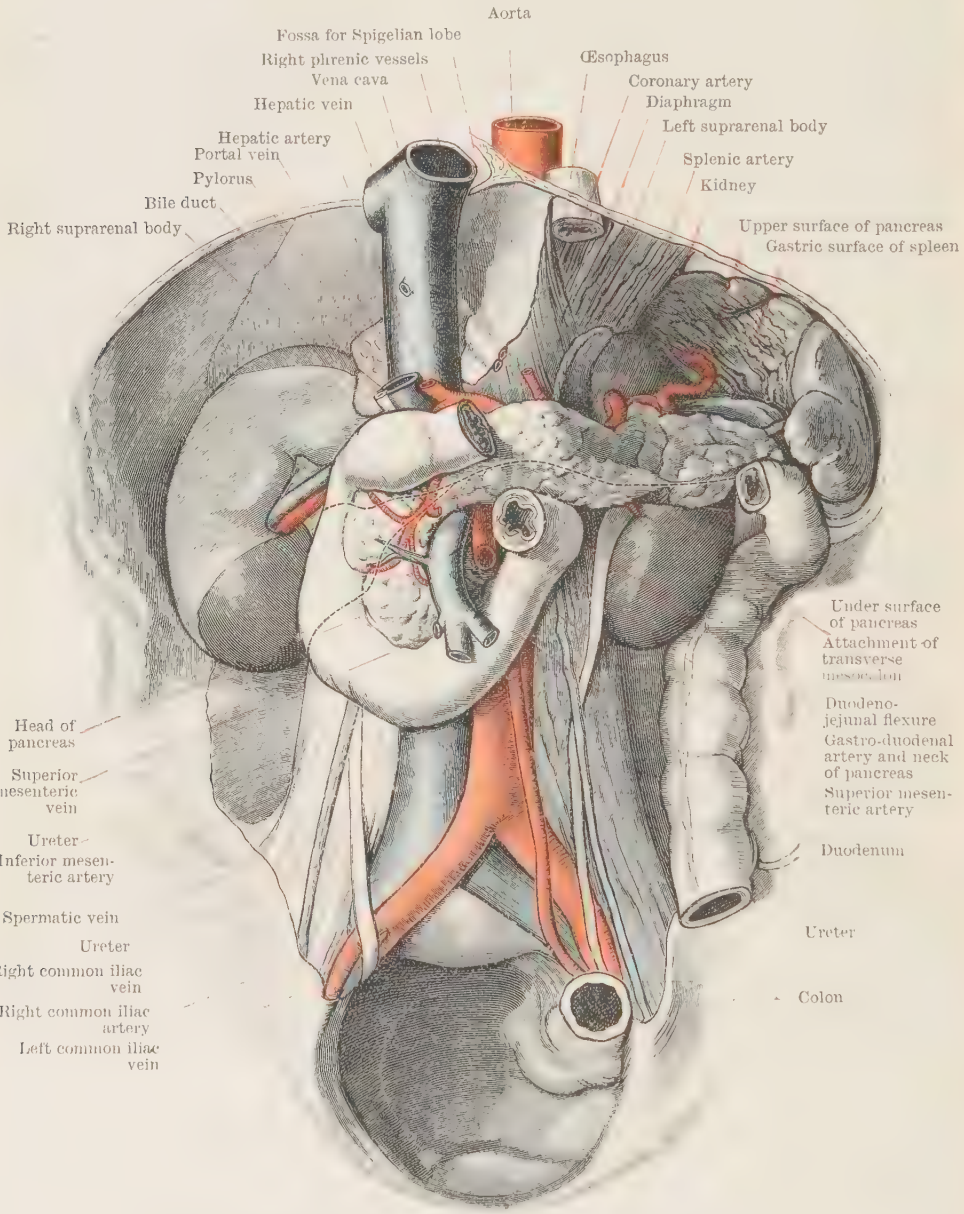

FIG. 757.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and the fossa for the Spigelian lobe. In taking out the liver, the vena cava was left behind. The stomach-bed is well shown. (From a body hardened by injection of chromic acid.)

stated to average about 1½ inches when empty, but it may be as much as two inches when distended.

**Relations.**—The **first or superior portion** (pars superior) begins at the pylorus opposite the first lumbar vertebra. From this it runs to the right, and then backwards, beneath the liver when the stomach is empty, but directly backwards

when it is full; and ends at the neck of the gall-bladder by turning downwards and passing into the second part. Its length varies from about $1\frac{1}{2}$ to 2 inches (3·7 to 5·0 cm.), and is said to be greater when the stomach is empty than when distended.

Its relations (Figs. 757 and 758) are as follows:—*Above and in front* lies the quadrate lobe of the liver, which hangs downwards and to the right over the tube. *Below*, it rests on the head and neck of the pancreas (the latter running up behind it for a little way). *Behind it*, close to the pylorus, the portal vein ascends to the liver, and the bile duct with the gastro-duodenal artery passes downwards. Further to the right, as it bends backwards, it lies against the right side of the vena cava.

Its *peritoneal relations* for about an inch from the pylorus are the same as those of the pyloric end of the stomach, that is to say, both the anterior and posterior

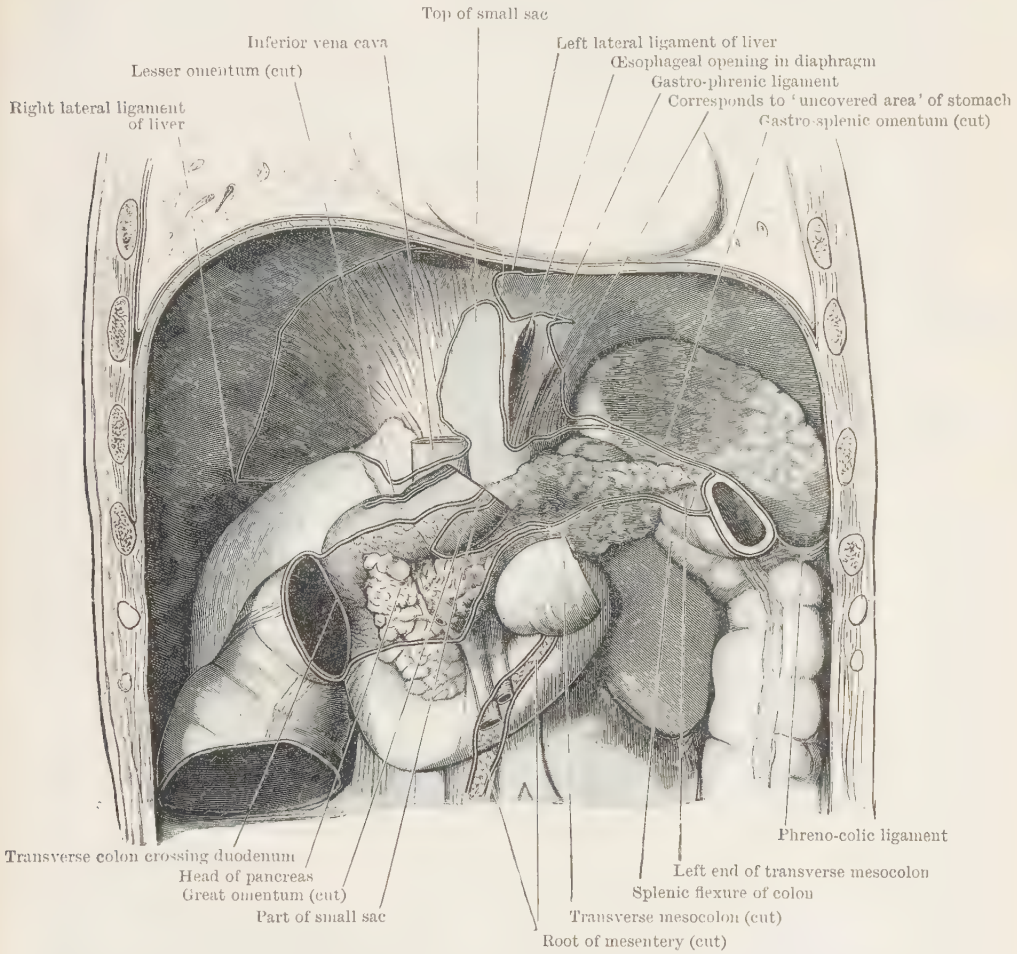

FIG. 758.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

From a body hardened by injections of formalin. In removing the liver, stomach, and intestines the lines of the peritoneal reflexions were carefully preserved. The peritoneum is coloured blue.

surfaces are covered, and the lesser and great omenta are attached to its upper and lower borders respectively (Fig. 758). Beyond this, however, only the anterior surface has a serous coat.

The peritoneal covering of the first half of the posterior surface is derived from a diverticulum of the small sac which runs to the right behind the duodenum for the distance mentioned.

When the stomach is distended, the first inch of the duodenum—which is movable on account of its complete peritoneal covering—is carried to the right with the pylorus, and thus brought

into line with the second or terminal half, which is always directed backwards. Hence the whole of the first portion of the duodenum is directed backwards when the stomach is full.

The **second** or **descending portion** (pars descendens) begins at the neck of the gall-bladder, passes down behind the transverse colon, and ends at the right side of the third or fourth lumbar vertebra. In length it measures 3½ or 4 inches (8·7 to 10 cm.).

*In front*, it is crossed about its middle by the beginning of the transverse colon (Fig. 758). Above the colon, it is in contact with the narrow end of the gall-bladder and below it with the coils of the small intestine. *Behind*, it is connected by areolar tissue to the inner part of the right kidney, with its ureter and renal vessels; it is also related, as a rule, to the right psoas muscle below the kidney (Fig. 757). To its *outer or right side* lies the liver (here presenting the duodenal impression) above, and often the ascending colon below. To its *inner side* are the inferior vena cava and the head of the pancreas, this latter overlapping it somewhat in front.

The common bile duct, after passing down behind the first portion of the duodenum, descends between the head of the pancreas and the second portion, nearly as far as its middle; here it is joined by the pancreatic duct, and the two, piercing the wall of the duodenum obliquely, open by a common orifice on its inner aspect, about 3½ to 4 inches (8·7 to 10 cm.) beyond the pylorus.

*Peritoneal relations.*—There is no peritoneum on the posterior or deep surface of this part, whilst its superficial or anterior surface is covered, except where it is crossed by the colon (Fig. 758).

When the beginning of the transverse colon is completely covered by peritoneum, and has a mesentery (a condition which often seems to be determined by a liver large in the vertical direction), the whole of the anterior surface, with the exception of the insignificant area between the two layers of the transverse mesocolon, is covered by the peritoneum.

On the other hand, when this part of the colon has no mesentery, it lifts the peritoneum off the front of the duodenum, and leaves a considerable "uncovered area," which is united by areolar tissue to the back of the colon.

The **third** or **inferior portion** (pars inferior) begins at the right side of the third or fourth lumbar vertebra. From this it first runs more or less transversely to the left across the vena cava (Fig. 757) for one or two inches, and then passes very obliquely, or even vertically, upwards in front of the aorta and left psoas muscle. Finally, having reached the lower surface of the pancreas, it bends forwards, and passes into the jejunum. Owing to the different directions which they take, we can recognise two divisions, a transverse and an ascending terminal, in this portion of the duodenum (Fig. 757).

*In front*, it is crossed (about the junction of its two divisions) by the superior mesenteric vessels, and also by the root of the mesentery (Fig. 758). On each side of this it is covered by coils of small intestine. *Behind*, its horizontal portion lies on the vena cava; its ascending portion on the aorta, the left renal vessels, and the left psoas muscle, all of which separate it from the vertebral column. *Above*, it is closely applied in its whole extent to the head of the pancreas. The *left side* of the *ascending terminal part*, which is free, lies in contact with some coils of the small intestine.

*Peritoneal relations.*—The third portion of the duodenum is covered by peritoneum on its anterior surface throughout, except where it is crossed by the superior mesenteric vessels and the root of the mesentery which contains them (Fig. 758). In addition, its ascending terminal portion is also clothed by this membrane on its left side; and here are usually found one or two small peritoneal pouches known as the **duodenal fossæ**.

The attachment of the root of the mesentery begins above quite close to the duodeno-jejunal flexure, on the front of the duodenum; from this it runs down on the anterior aspect of the ascending terminal part, and finally leaves the duodenum about the union of the two divisions of its third portion.

**Duodenal Fossæ.**—In the neighbourhood of the ascending part of the third portion of the duodenum are found three well-known fossæ of the peritoneum which are of some surgical interest; these are the superior and inferior duodenal and the paraduodenal fossæ (Fig. 759). Other rarer forms are occasionally present.

When the ascending terminal part of the duodenum is drawn over to the right, and the angle between its left side and the posterior abdominal wall examined, one or two triangular folds of peritoneum will generally be found crossing over this angle from the duodenum to the abdominal wall. Each fold has one edge attached to the duodenum, another to the parietal peritoneum at the left of the duodenum, whilst the third is free, and bounds the opening of a small pouch which lies behind the fold. One of these, the *superior duodenal fold*, is situated near the termination of the duodenum, with its apex directed up and its free margin down. It sometimes contains between its two layers the termination of the inferior mesenteric vein. Behind it lies the **superior duodenal fossa**, the opening of which looks downwards, and will usually admit the tip of a finger (Fig. 759). The second, known as *the inferior duodenal fold*, is placed lower down, at the side of the same part of the duodenum. Its free border is directed upwards, as is the mouth of the **inferior duodenal fossa**, which lies behind it. This latter is larger and more constant than the superior duodenal fossa, and is present in 75 per cent of bodies, whilst the superior is present in 50 per cent (Jonnesco).

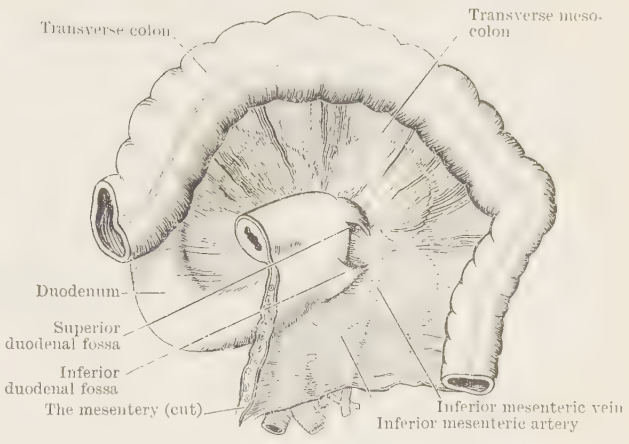

FIG. 759.—THE DUODENAL FOSSÆ AND FOLDS.

The transverse colon and mesocolon have been thrown up, and the mesentery has been turned to the right and cut. The paraduodenal fossa (of Landzert) is situated to the inner side of the inferior mesenteric vein, between it and the terminal part of the duodenum. It is not shown in the illustration.

**Paraduodenal Fossa** (fossa of Landzert).—This fossa, which is best seen in the infant, is placed some distance to the left of the terminal part of the duodenum. It is produced by the inferior mesenteric vein raising up a fold of peritoneum, as it runs along the outer side of the fossa, and then inwards above it (see Fig. 759, where the vein, but not the fossa, is shown). It is limited below by a special fold (the mesenterico-mesocolic fold). According to Moynihan, this is the only fossa to the left of the duodenum capable of developing into the sac of a hernia; and when this occurs, the inferior mesenteric vein always lies in the anterior margin of the orifice of the sac (accompanied for some distance by the ascending branch of the left colic artery).

In addition to the above, a duodeno-jejunal fossa at the front of the duodeno-jejunal flexure, and five other fossæ, have—perhaps unnecessarily—been described in this region.

**Peritoneal Relations of the Duodenum.**—Whilst the relations of the peritoneum to the second and third portions of the duodenum are usually described as in the foregoing account, it should perhaps be pointed out, that it is not really the front, but the right half of the circumference of the descending portion which has a serous coat. Similarly, it is the lower and anterior half of the circumference of the transverse part of the third portion which is clothed by peritoneum, whilst considerably more than half of the circumference of its ascending terminal part is covered; for the peritoneum forms a fold running in behind this part, in addition to covering its left side and half its anterior aspect.

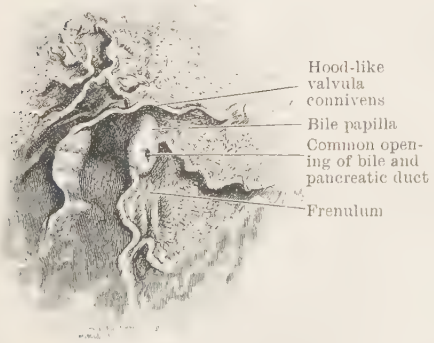

FIG. 760.—THE BILE PAPILLA IN THE INTERIOR OF THE DUODENUM.

**Interior of Duodenum.**—No valvulæ conniventes are found in the duodenum for an inch or two beyond the pylorus. Here they begin; at first as low, scattered, and irregular folds; further down, they gradually become larger, more regular, and more numerous; and by the time the middle of the descending stage is reached they have attained a considerable develop-

ment. In the lower part of the duodenum the folds are large, prominent, and closely set.

On the inner aspect of the descending portion, about its middle—namely, $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.) beyond the pylorus—is seen a prominent papilla, on which the bile and pancreatic ducts open by a common orifice (Fig. 760). This is known as the **bile papilla** (papilla duodeni; caruncula major of Santorini).

The bile papilla is placed beneath, and protected by, a prominent, hood-like valvula conniven, which is situated immediately above it. From its lower margin a firm ridge of the mucous membrane (the plica longitudinalis duodeni) descends for a considerable distance, and acts as a frenum, which fixes the papilla and directs its apex somewhat downwards (Fig. 760). The papilla is prominent, and nipple or dome-shaped, and at its summit is placed the small orifice, which will usually admit the point of a pencil; the whole bears a close resemblance to the nozzle of a perfume-spray.

Nearly an inch higher up, and invariably on the ventral side of the bile papilla (sometimes as much as a $\frac{1}{2}$ to $\frac{3}{4}$ inch distant), is seen a second and smaller papilla (the caruncula minor of Santorini), at the point of which is placed the very small orifice of the accessory pancreatic duct. This second papilla seems to be constantly present, although sometimes so small that it may easily escape detection unless carefully sought for. When well developed, it may have a hood-like valvula connivens and a little frenulum, like those of the bile papilla.

**Structure of the Duodenum.**—The **peritoneal coat**, which is incomplete, has already been described in detail, in connexion with each division of the duodenum.

The **muscular coat** is well developed, and is pierced by the bile and pancreatic ducts, but otherwise calls for no special description.

The **submucosa** differs from that of the rest of the small intestine, in that it contains, especially in the upper half of the duodenum, the **glands of Brunner** (glandulæ duodenales). These are small acinotubular glands, closely resembling the pyloric glands of the stomach, which lie in the submucous coat, and send their ducts through the muscularis mucosæ to open on the surface between Lieberkühn's glands, or sometimes into these glands themselves (Fig. 754). They can be exposed by removing the peritoneal and muscular coats, and also some of the submucosa, when they appear as little round or flattened masses of a reddish gray colour, varying in size from $\frac{1}{50}$th to $\frac{1}{12}$th of an inch in diameter (·5 to 2·0 mm.). They form an almost continuous layer as far as the opening of the bile duct; beyond this they diminish progressively, and completely disappear near the duodeno-jejunal flexure.

The **mucous membrane**, which is thicker in the duodenum than in any other part of the small intestine, is covered throughout with broad short villi. Its other characteristics have been already fully described.

**Various Forms of Duodenum.**—Three different types of duodenum have been described—(1) The **annular**, in which the curves separating the various portions are open, and the two extremities come fairly close to one another. (2) The **U-shaped**, in which the transverse part of the third portion is very long, and the ascending portion nearly vertical; and (3) the **V-shaped** duodenum, in which the transverse part of the third portion is very short or absent.

**Duodenal Pouch.**—A diverticulum of the duodenum, arising from its left side just above the opening of the bile duct, and running into the substance of the pancreas, is occasionally found. It is possibly connected with one of the outgrowths of the duodenum from which the pancreas is developed in the embryo.

**Vessels and Nerves.**—The duodenum receives its blood from the superior and inferior pancreatico-duodenal arteries, branches of the gastro-duodenal and superior mesenteric arteries respectively. The blood is returned by the corresponding veins, the superior of which opens into the superior mesenteric, and the inferior into the beginning of the portal vein.

The **lymphatics** pass to a set of glands placed along the pancreatico-duodenal arteries, and thence to the cœliac glands.

The **nerves** come from the solar plexus of the sympathetic.

**Duodeno-jejunal Flexure.**—When the ascending terminal portion of the duodenum reaches the under surface of the pancreas, at a point opposite the left side of the first or second lumbar vertebra, it turns abruptly forwards, downwards, and to the left, and passes into the jejunum. This abrupt bend is known as the **duodeno-jejunal flexure.** Unlike the rest of the duodenum, which is subject to considerable variations in position in different individuals, the duodeno-jejunal flexure is fixed by a thin band of unstriped muscle, which is attached above to the strong connective tissue around the cœliac axis, as well as to the left crus of the diaphragm, and below joins the muscular coat of the duodenum at the flexure. This band is known as the **suspensory muscle of the duodenum** (musculus suspensorius duodeni—Treitz).

The course taken by the gut at the duodeno-jejunal flexure is variable: the chief directions in their order of frequency are—(1) downwards, forwards, and to the left; (2) directly forwards and downwards; (3) to the left, and then downwards; (4) forwards and to the right (Harman).

Some of the fibres of the suspensory muscle are said by Lockwood to pass into the mesentery, and he consequently calls it "the suspensory muscle of the duodenum and mesentery proper."

## THE JEJUNUM AND ILEUM.

The upper two-fifths, that is, about 8 feet of the small intestine beyond the duodenum, are known as the **jejunum** (intestinum jejunum). The succeeding three-fifths, which usually measures about 12 feet, constitute the **ileum**. The ileum opens into the large intestine at the junction of the cæcum and ascending colon, where its orifice is guarded by the ileo-cæcal valve.

Both the jejunum and ileum are connected to the parietes by a large fold of

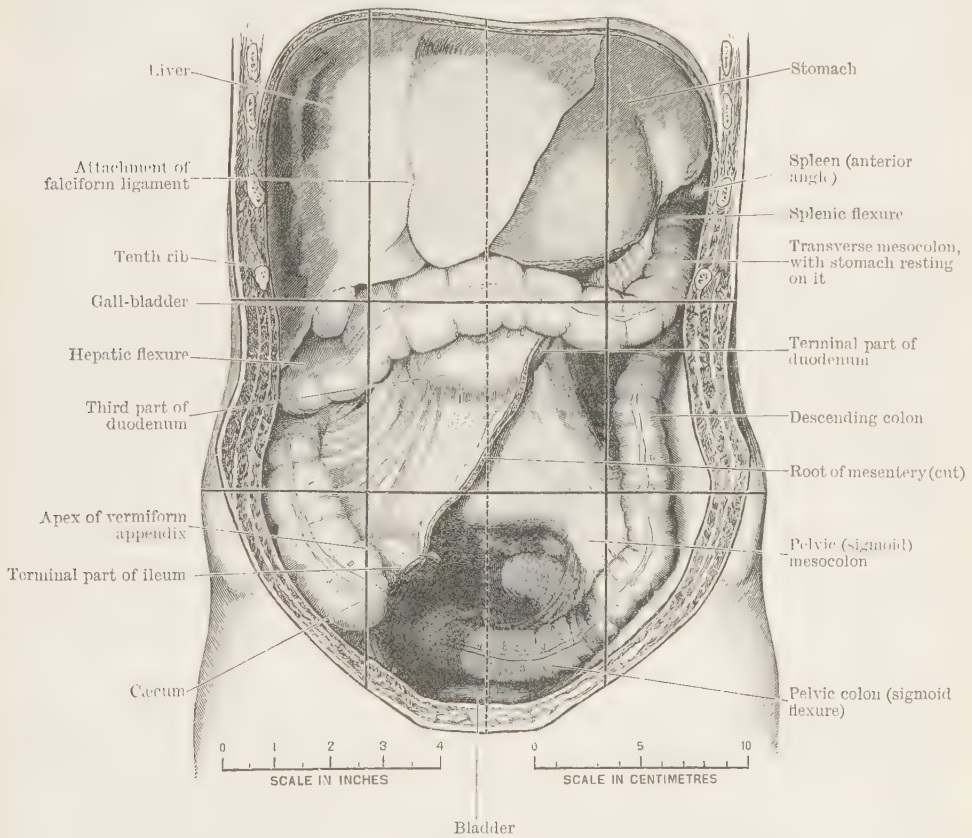

FIG. 761.—THE ABDOMINAL VISCERA AFTER THE REMOVAL OF THE JEJUNUM AND ILEUM (from a photograph of the same body as depicted in Fig. 739). The transverse colon is much more regular than usual. Both the liver and cæcum extend lower down than normal. The subdivisions of the abdominal cavity are indicated by dark lines.

peritoneum—*the mesentery*—which conveys vessels and nerves from the posterior abdominal wall to these divisions of the intestine.

The part of the tube to which the mesentery is connected is known as the mesenteric or attached border; the opposite side is the free border.

The **mesentery** (mesenterium) is a broad fan-shaped fold, composed of two layers of peritoneum, which connects the small intestine to the back of the abdomen. One border of the fold is wide and contains the intestine within it (Fig. 753). The other, known as the *root of the mesentery* (radix mesenterii), is comparatively narrow, being only 6 or 7 inches wide, but it is much thicker than the part near the gut, for it contains between its layers a considerable amount of fatty subperitoneal tissue, in addition to the large vascular trunks passing to

the intestine. The root is attached to the posterior abdominal wall along an oblique line, extending approximately from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 761). In this course its line of attachment passes from the duodeno-jejunal flexure down over the front of the terminal part of the duodenum, then obliquely across the aorta, the inferior vena cava, the ureter, and psoas muscle, to reach the right iliac region.

The opposite border of the mesentery is frilled out to an enormous degree, so that, while the root measures but 6 or 7 inches, the free border is extended to some 20 feet, thus resembling a fan, one border of which may be twenty or thirty times as long as the other. The length of the mesentery, measured from its root to the attached edge of the intestine directly opposite, usually measures at its longest part about 6 inches (8 or 9 inches, Treves and Lockwood).

*Between the two layers* of the mesentery (Fig. 753) are contained (*a*) the intestinal branches of the superior mesenteric vessels, accompanied by the mesenteric nerves and lymphatics; (*b*) the mesenteric lymphatic glands, which vary from 40 to 150 in number; (*c*) a considerable amount of fatty connective tissue, continuous with the extra-peritoneal areolar tissue; and (*d*) the intestine itself.

The peritoneum from the right side of the mesentery passes out on the posterior abdominal wall to clothe the ascending colon, and, above, it is connected by a fold with the transverse mesocolon. That of the left side, similarly, passes across the parietes to the descending and iliac colons.

The mesentery begins above, immediately beyond the ending of the duodenum—that is, in the angle of the duodeno-jejunal flexure—and it ends below in the angle between the ileum and ascending colon. It is very short at each end, but soon attains the average length. Its longest part goes to the portion of the small intestine situated between two points, one six feet, the other eleven feet from the duodenum (Treves).

Whilst the root of the mesentery pursues at its attachment an almost straight line from one end to the other, if cut across a very short distance from the posterior abdominal wall, it will here be found to form a wavy or undulating line. Further out still this condition becomes more and more marked; and finally, if the bowel be removed by cutting through the mesentery close to its attachment to the intestinal wall, it will be seen that its free edge is not only undulating, but is frilled or plaited to an extreme degree. When shown in this way, it is found that the plaiting or folding is not quite indiscriminate, but that the main folds, of which there are usually six, run alternately to the right and left. As a rule, the first fold runs to the left from the duodeno-jejunal flexure, and goes to a coil of jejunum which lies under the transverse mesocolon, and helps to support the stomach (this coil has been already referred to, page 1053). The second fold passes to the right, the third to the left, and so on up to the fifth and sixth, which are usually small. From the margins of these primary folds secondary folds project in all directions, and from these again even a third series may be formed.

This order is of course by no means constant, but if the intestine be removed from a hardened body in the way suggested, without disturbing the mesentery, it will be found to be arranged with more or less regularity, on some such plan as that indicated.

**Arrangement of Coils of Small Intestine.**—Although the greatest variety is found in the disposition of the small intestine, and it is impossible to state in what regions of the abdomen the different parts of the tube will be found, still it may be said that in general the jejunum (as might be expected from the position at which it begins) is placed above and to the left, in reference to the ileum, which latter lies below and to the right. Again, the upper part of the jejunum is usually situated to the left of the duodeno-jejunal flexure, in contact with the under surface of the pancreas and transverse mesocolon; and, similarly, the terminal part of the ileum almost always lies in the pelvis, from which it passes up over the right side of the pelvic brim to reach the ileo-cæcal orifice. Another portion of the small intestine is not uncommonly found in the pelvis; this is the part with the longest mesentery, and lies between two points, six and eleven feet respectively from the duodenum (Treves).

**Differences between Jejunum and Ileum.**—If the small intestine be followed down from the duodenum to the cæcum no noticeable change in appearance will be found at any one part of its course, to indicate the transition from jejunum to ileum; for the one passes insensibly into the other. Nevertheless, a gradual change takes place, and if typical parts of the two, namely, the upper portion of the jejunum and the lower portion of the ileum, be examined, they will be found to present characteristic differences, which are set forth in the following table:—

| Jejunum. | Ileum. |
|---|---|
| Wider, $1\frac{1}{2}$ to $1\frac{1}{4}$ inch in diameter. | Narrower, $1\frac{1}{4}$ to 1 inch in diameter. |
| Wall, thicker and heavier. | Wall, thinner and lighter. |
| Redder and more vascular. | Paler and less vascular. |
| Valvulæ conniventes well developed. | Valvulæ conniventes absent or very small. |
| Peyer's patches, few and small. | Peyer's patches, large and numerous. |

The villi are also said to be shorter and broader in the jejunum, more slender and filiform in the ileum (Rauber).

The terminal portion of the ileum, after crossing the brim of the pelvis, runs upwards, and also slightly backwards and to the right, in close contact with the cæcum, until the ileo-cæcal orifice is reached.

**Meckel's Diverticulum** (diverticulum ilei).—This is a short wide protrusion which is found springing from the lower part of the ileum in a little over 2 per cent of the bodies examined. It is usually about 2 inches long, and of the same width as the intestine from which it comes off. Most commonly it is found about $2\frac{3}{4}$ feet from the ileo-cæcal valve, and opposite the termination of the superior mesenteric artery. As a rule, it runs at right angles to the gut, and its end is free; but occasionally it is adherent either to the abdominal wall, the adjacent viscera, or the mesentery, when it may be the cause of strangulation of the intestine.

The diverticulum is due to the persistence of the proximal portion of the vitelline (or vitello-intestinal) duct, which connects the primitive intestine of the embryo with the yolk sac. In shape it may be cylindrical, conical, or cord-like, and it may present secondary diverticula near its tip. It arises most frequently from the free border of the intestine, but it sometimes comes off from the side. It runs at right angles to the gut most commonly, but it may assume any direction, and it often is provided with a mesentery. In 3302 bodies specially examined with reference to its existence, it was present in 73, or 2·2 per cent, and it appeared to be more common in the male than in the female. In 59 out of the 73 cases its position with reference to the end of the ileum was examined: its average distance from the ileo-cæcal valve was $32\frac{1}{2}$ inches measured along the gut, the greatest distance being 12 feet, and the smallest 6 inches. In 52 specimens the average length was 2·1 inches, the longest being $5\frac{1}{4}$ inches, the shortest $\frac{1}{2}$ inch. The diameter usually equals that of the intestine from which it springs; but occasionally it is cord-like, and pervious only for a short way; on the other hand, it may attain a diameter of $3\frac{3}{4}$ inches. (The foregoing results have been compiled from the reports of The Collective Investigation of the Anatomical Society of Great Britain and Ireland—L. J. Mitchell, Kelynack, Rogie, and Augier.)

**Vessels and Nerves of the Jejunum and Ileum.**—The **arteries** for both the jejunum and ileum—the vasa intestini tenuis—come from the superior mesenteric, and are contained between the two layers of the mesentery. After breaking up and forming three tiers of arches, the terminal branches (Fig. 753) reach the intestine, where they bifurcate, giving a branch to each side of the gut. These latter run transversely round the intestines, at first under the peritoneal coat; soon, however, they pierce the muscular coat and form a plexus in the submucosa, from which numerous branches pass to the mucous membrane, where some form plexuses around the glands of Lieberkühn, whilst others pass to the villi. The **veins** are similarly disposed, and the blood from the whole of the small intestine beyond the duodenum is returned by the superior mesenteric vein, which joins with the splenic to form the portal vein.

The **lymphatics** of the small intestine (known as lacteals) begin in the villi, and also as lymphatic sinuses surrounding the bases of the solitary glands; a large plexus is formed in the submucosa, a second between the two layers of the muscular coat, and a third beneath the peritoneum. The vessels from all these pass up in the mesentery, being connected on the way with the numerous (from 40 to 150) **mesenteric glands**, and finally unite to form one, or a few, intestinal lymphatic trunks, which open into the receptaculum chyli.

The **nerves** come from the solar plexus, through the superior mesenteric, which latter accompanies the superior mesenteric artery between the layers of the mesentery, and thus reaches the intestine. Some of the fibres are derived ultimately from the right vagus. The nerve-fibres are non-medullated, and form, as in other parts of the canal, two gangliated plexuses—that of Auerbach in the muscular coat, and the plexus of Meissner in the submucosa.

**Structure.**—The **serous coat** is complete in all parts of the jejunum and ileum. The **muscular coat** is thicker in the jejunum, and grows gradually thinner as it is traced down along the ileum. The **submucosa** contains the bases of the solitary glands (Fig. 754), but otherwise calls for no special remark. The **mucous coat** is thicker and redder above, in the jejunum, thinner and paler in the ileum. It is covered throughout by villi, which are shorter and broader in the jejunum, longer and narrower in the ileum. In its whole extent it is closely beset with Lieberkühn's follicles, and numerous solitary glands are

seen projecting on its surface. Peyer's patches are particularly large and numerous in the ileum; they are fewer, smaller, and usually circular, in the jejunum. Finally, the mucous membrane forms valvulæ conniventes, which are much more prominent in the jejunum; they are smaller and fewer in the upper part of the ileum, and usually disappear a little below its middle.

## THE LARGE INTESTINE.

The ileum is succeeded by the large intestine (intestinum crassum), which begins on the right side, some 2½ inches below the ileo-cæcal junction, and comprises the following parts:—

1. The **cæcum,** a wide, short cul-de-sac, consisting of the portion of the large bowel below the ileo-cæcal junction. It lies in the right iliac region, and from its inner and back part a worm-shaped outgrowth, the **vermiform process,** is prolonged (Fig. 761).

2. The **ascending colon** extends from the cæcum, up in the right side of the abdomen, to the liver: here the gut bends to the left, forming the **hepatic flexure,** which connects the ascending colon to the transverse colon.

3. The **transverse colon** is a long loop of intestine which arches across the abdominal cavity in an irregular manner. It ends at the lower extremity of the spleen, where it turns downward, forming the **splenic flexure,** and passes into the descending colon.

4. The **descending colon** runs down on the left side, from the splenic flexure to the iliac crest.

5. The **iliac colon** extends from the crest of the ilium to the brim of the pelvis, where it is succeeded by the pelvic colon.

6. The **pelvic colon** is a large loop of intestine which is usually found in the pelvis. The iliac and pelvic portions of the colon taken together are commonly described as the *sigmoid flexure* of the colon.

7. The **rectum,** the terminal part of the large bowel, succeeds the pelvic colon, and ends at the **anal orifice.**

In its course the large bowel is arranged in an arched manner around the small intestine, which lies within the concavity of its curve (Fig. 739).

In *length,* the great intestine is equal to about one-fifth of the whole intestinal

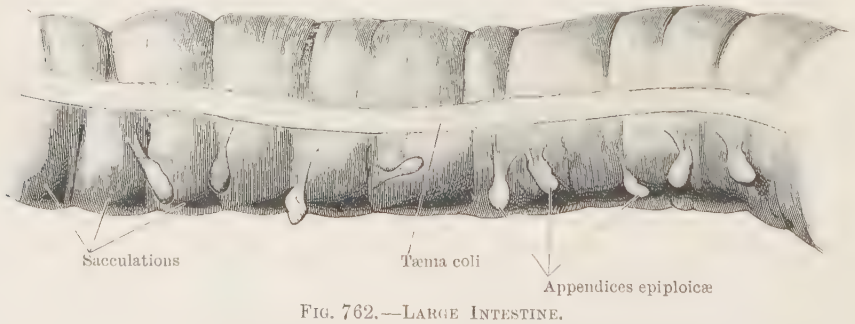

FIG. 762.—LARGE INTESTINE.

A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—sacculations, tæniæ, and appendices epiploicæ—are shown.

canal, and usually measures between 5 and 5½ feet (180 to 195 cm.). Its *breadth* is greatest at the cæcum, and from this—with the exception of a dilation at the rectum—it gradually decreases to the anus. At the cæcum it measures, when distended, about 3 inches (75 mm.) in diameter; beyond this it gradually diminishes, and measures only 1½ inch (37 mm.) or less in the descending and iliac divisions of the colon.

The large intestine, with the exception of the rectum and vermiform appendix, may be easily distinguished from the regularly cylindrical small intestine by (*a*) the presence of three longitudinal bands—the **tæniæ coli**—running along its surface (Fig. 762); (*b*) by the fact that its walls are sacculated; and (*c*) by the presence of numerous little peritoneal processes, known as **appendices epiploicæ,** projecting

from its serous coat. In addition, the larger intestine is usually wider than the small, but too much reliance cannot be placed on this character, for the jejunum is often—indeed, generally—wider than the empty and contracted descending colon.

**Tæniæ Coli.**—In the large bowel, unlike the small, the longitudinal fibres of the muscular coat do not form a complete layer, continuous all round the tube, but, on the contrary, are broken up (Fig. 762) into three bands, known as the **tæniæ coli**. These bands, which are about $\frac{1}{4}$ inch (6 mm.) wide, begin at the base of the vermiform appendix, and run along the surface of the gut at nearly equal distances from one another until the rectum is reached. Here they spread out and form a layer of longitudinal muscular fibres, which is continuous all round the tube (see p. 1087). The bands are about one-sixth shorter than the intestine to which they belong; consequently, in order to accommodate the bowel to the length of the tæniæ, the gut is tucked up, giving rise to a sacculated condition (Fig. 762). Three rows of pouches or saccules are thus produced, along the length of the tube, between the tæniæ. If the tæniæ be dissected off, the sacculations disappear, the intestine becomes cylindrical, and at the same time about one-sixth longer.

The **appendices epiploicæ** (Fig. 762) are little processes or pouches of peritoneum, generally more or less distended with fat, except in emaciated subjects, which project from the serous coat along the whole length of the large intestine, with the exception of the rectum proper.

When the interior of a piece of distended and dried large intestine is examined, its saccules appear as rounded pouches (haustra), separated by crescentic folds (plicæ semilunares coli), corresponding to the creases on the exterior separating the saccules from one another.

The position of the three tæniæ on the intestines is as follows :—On the ascending, descending, and iliac colons one tænia lies on the anterior aspect of the gut, and two behind, namely, one to the outer (postero-external), the other to the inner side (postero-internal). It is chiefly along the first of these (the anterior) that the appendices epiploicæ are found. On the transverse colon their arrangement is different, but is rendered exactly similar by turning the great omentum, with the colon, up over the thorax. On the transverse colon in the natural position, the anterior tænia of the ascending and descending colons becomes the posterior (or postero-inferior, tænia libera), the postero-external becomes the anterior (or omental), and the postero-internal the superior or mesocolic. The anterior and postero-external tæniæ of the iliac colon pass below on to the front of the pelvic colon and rectum.

In formalin-hardened bodies portions of the large intestine, but particularly of the descending and sigmoid colons, are often found fixed in what appears to be a state of contraction, when they are reduced to a diameter of about $\frac{5}{8}$ or $\frac{3}{4}$ of an inch (16 to 19 mm.). Under similar conditions parts of the small intestine are found correspondingly reduced.

The appendices epiploicæ, although generally said to be absent in the fœtus, can be distinctly seen as early as the seventh month, but at this time they contain no fat.

**Structure of the Large Intestine.** — The **serous coat** is complete on the vermiform appendix, cæcum, transverse colon, and pelvic colon; incomplete on the ascending, descending, and iliac divisions of the colon and on the rectum. It will be described in detail with each of these portions of the intestine.

The **mucous coat** is of a pale, or yellowish, ash colour in the colon, but becomes much redder in the rectum. Unlike that of the small intestine, its surface is smooth, owing to the absence of villi, but it is closely studded with the orifices of numerous large Lieberkühn's glands. Solitary glands are also numerous, particularly in the vermiform process (Fig. 767).

**Vessels and Nerves.**—The cæcum and vermiform appendix receive their blood from the **ileo-colic artery**; the ascending colon from the **right colic**; and the transverse colon from the **middle colic** which lies in the transverse mesocolon. These are all branches of the superior mesenteric artery. The descending colon is supplied by the **left colic**, and the iliac and pelvic colons by the **sigmoid arteries**, branches of the inferior mesenteric. The rectum derives its blood from the three **hæmorrhoidal arteries**, which will be described with that division of the gut.

The **veins** correspond to the arteries, and join the inferior and superior mesenteric vessels, which send their blood into the portal vein.

The **lymphatics** begin in the mucous membrane, and form a large plexus in the submucosa; leaving the gut, those of the cæcum, ascending, transverse, and upper half of the descending colon, pass to the mesocolic glands, which lie behind the ascending and descending divisions of the colon and between the layers of the transverse mesocolon. The lymphatics from the lower half of the descending, and from the iliac and pelvic colons, join the left lymphatic trunk of the lumbar glands. Those of the rectum will be described later.

**Nerves.**—The nerves come from the superior mesenteric plexus, an offshoot of the solar plexus, and from the inferior mesenteric, a derivation of the aortic plexus. The arrangement is similar to that of the nerves of the small intestine.

## THE CÆCUM AND APPENDIX.

**Cæcum.**—After leaving the pelvic cavity, as already described, the terminal portion of the small intestine passes upwards, backwards, and to the right, and opens, by the ileo-cæcal orifice, into the large intestine some 2½ inches from its lower end. The portion of the large gut which lies below the level of this orifice is known as the **cæcum** (caput cæcum coli). *In shape* (Fig. 763) it is a wide, unsymmetrical, or lop-sided cul-de-sac, furnished with the tæniæ and sacculations usually found in the large intestine. Its lower end or *fundus* is directed downwards and inwards, and usually rests on the front of the right psoas muscle, close to the brim of the pelvis; whilst the opposite end is directed upwards and outwards, and is continued into the ascending colon.

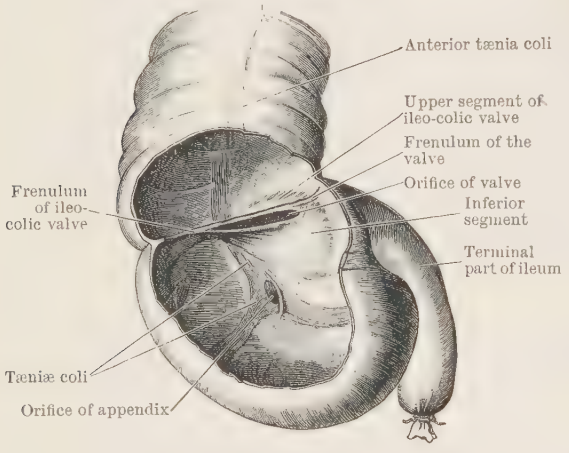

FIG. 763.—CÆCUM SHOWING ILEO-CÆCAL VALVE.
The cæcum has been distended with air and dried, and a portion of its anterior wall has been removed.

Its unsymmetrical form is due to the fact that the outer and inner portions of the organ undergo an unequal development in the child. The inner (or inner and posterior) section lags behind, whilst the outer (or outer and anterior) division grows much more rapidly, and, projecting downwards, soon comes to form the lower end or fundus of the cæcum. As a result the original extremity of the gut, with the vermiform process springing from it, is hidden away behind and to the inner side of the fundus.

In *length* the distended cæcum usually measures about 2½ inches (60 mm.); whilst its *breadth* is usually more, and averages about 3 inches (75 mm.).

**Position.**—It is situated, when normal, almost entirely within the right iliac region of the abdomen, immediately above Poupart's ligament; but its lower end projects inwards in front of the psoas and reaches the hypogastrium (Fig. 769). On the other hand, it is sometimes found, even when quite healthy, high up in the right lumbar region (owing to the persistence of the fœtal position), or hanging over the pelvic brim and dipping into the pelvic cavity to varying extents.

In the great majority of cases the cæcum is completely covered by peritoneum on all aspects, and lies quite free in the abdominal cavity. In a small proportion, namely, about 6 or 7 per cent of bodies, the posterior surface (probably as a result of adhesions) is not completely covered, but over a greater or less portion of its extent is bound down to the posterior abdominal wall by connective tissue.

**Relations.**—*Behind*, the cæcum rests on the ilio-psoas muscle; generally, too, on its own vermiform process and the external iliac artery. *In front*, it usually lies in contact with the anterior abdominal wall; sometimes, however, when the cæcum is empty, the small intestine intervenes. Its *outer side* is placed immediately above the outer half of Poupart's ligament (Fig. 769), whilst the *inner side* has the termination of the ileum lying in contact with it. On the inner and posterior aspect, but more on the former than the latter, the small intestine joins the cæcum. On the same aspect, and usually about 1¼ inches (31 mm.) lower down, the vermiform process comes off.

The *interior* of the cæcum corresponds in general appearance to that of the large intestine; but it presents two special features on the posterior part of its inner wall, namely, the **ileo-cæcal orifice**, guarded by the **ileo-cæcal**

**valve**, and below this the small opening of the **vermiform appendix**, both of which call for further notice.

**Ileo-cæcal Valve** (valvula coli). — Where the ileum enters the large intestine, the end of the small gut is, as it were, thrust through the wall of the large bowel, carrying with it certain layers of that wall, which project into the cæcum in the form of two folds, lying respectively above and below its orifice, and constituting the two segments of the ileo-cæcal valve (Fig. 765). The condition may be compared to a partial inversion or telescoping of the small into the large intestine: it must be added that the peritoneum and longitudinal muscular fibres of the bowel take no part in this infolding; on the contrary, they are stretched tightly across the crease produced on the exterior by the inversion, and thus serve to preserve the fold and the formation of the valve.

As seen from the interior, in specimens which have been distended and dried (Fig. 763), the valve is made up of two crescentic segments—an upper, in a more or less horizontal plane, forming the superior margin of the aperture; and a lower, which is also larger, placed in an oblique plane, and sloping upwards and inwards (*i.e.* towards the cavity of the cæcum). Between the two segments is situated the slit-shaped opening, which runs in an almost antero-posterior direction, with a rounded anterior and a pointed posterior extremity (Fig. 763). At each end of the orifice the two segments of the valve meet, unite, and are then prolonged around the wall of the cavity as two prominent folds—the **frenula** (frenula valvulæ coli). It is thought that when the cæcum is distended, and its circumference thereby increased, these frenula are put on the stretch, and, pulling upon the two segments of the valve, they bring them into apposition, and effect the closure of the orifice.

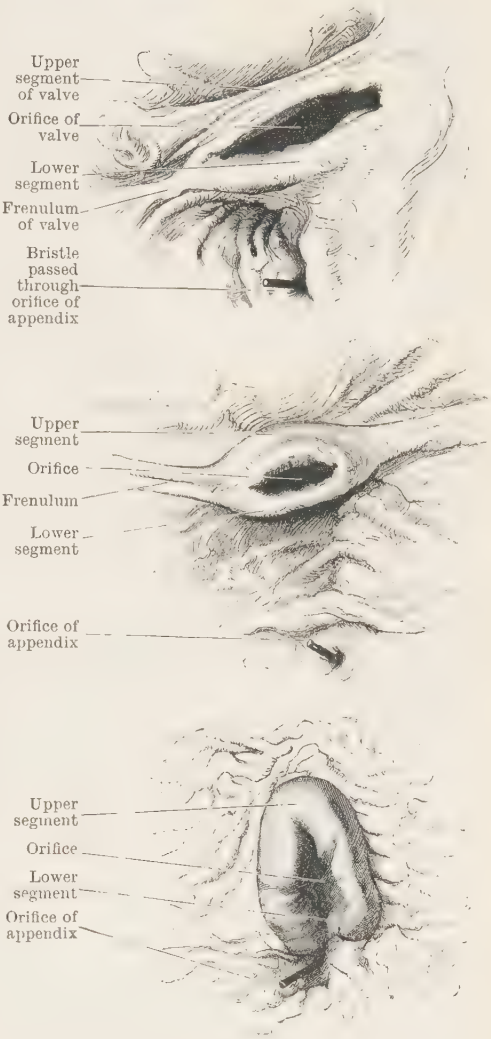

Fig. 764.—Three Forms of Ileo-cæcal Valve, from bodies hardened by intravascular injections of formalin.

The hardening was not so complete in the case of the highest of the three valves represented. In each a bristle is passed through the orifice of the vermiform appendix.

The **position of the ileo-cæcal orifice**, in the average condition, may be indicated on the surface of the body by the point of intersection of the intertubercular and Poupart lines. A point 1 to 1½ inches (2·5 to 3·7 cm.) lower down would correspond to the **orifice of the vermiform process**.

In bodies hardened *in situ* with formalin, the valve and orifice present an entirely different appearance (see Fig. 764, in which three different forms of hardened valves are shown), suggesting, much more closely than in the dried state, the appearance of telescoping or inversion mentioned above. In them also the two segments of the valve are much thicker and shorter, but they can always be distinguished, and are found to bear the same relation to one another as in the dried condition, although this may be obscured by foldings or rugæ. The aperture may be slit-like or rounded, with sloping or infundibuliform edges; the frenula are not so prominent at times; but the whole valve projects much more abruptly into the cavity of the cæcum than in the distended and dried specimen.

**Structure of the Ileo-cæcal Valve.**—Each segment of the valve is formed of an infolding of all the coats of the gut, except the peritoneum and the longitudinal muscular fibres, and consequently it consists of two layers of mucous membrane, with the submucosa and the circular muscular fibres between, all of which are continuous with those of the ileum on the one hand and of the large intestine on the other. The surface of each segment turned towards the small intestine is covered with villi, and conforms in the structure of its mucous membrane to that of the ileum; whilst the mucous membrane of the opposite side resembles the mucous coat of the large bowel.

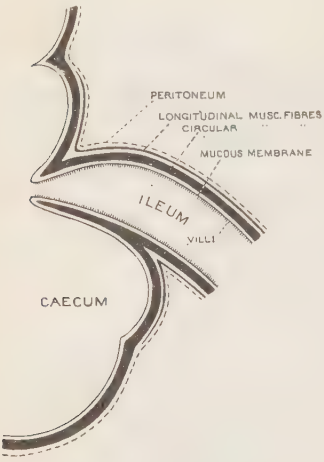

Fig. 765.—Diagrammatic Section through the Junction of Ileum with Cæcum, to show the Formation of the Ileo-cæcal Valve.

In the dried specimen the upper segment usually projects further into the cavity of the cæcum than the lower, so that the aperture appears to be placed between the edge of the lower segment and the under surface of the upper.

There is little doubt, as pointed out by Symington, that the efficiency of the ileo-cæcal valve is largely due to the oblique manner in which the ileum enters or invaginates the cæcum; this oblique passage alone, as in the case of the ureter piercing the wall of the bladder, would probably be sufficient to prevent a return of the cæcal contents. In the great majority of cases, when in position within the body, the ileum is perfectly protected from such a return, although when the parts are removed, and then distended with fluid, this often passes through the valve, and reaches the small intestine. Still, the efficiency of such a test, applied when the parts are deprived of their natural supports, cannot be relied upon.

The size of the segments of the valve, as seen in the dried condition, varies considerably; they are sometimes very imperfect; and even the absence of both has been recorded. But here again there is danger of falling into error, through examining the parts under such artificial conditions.

**Development of Cæcum and Appendix.**—The cæcum first appears in the embryo, at about the fifth week, as a small outgrowth of the wall of the primitive gut (mid-gut), not yet differentiated into small and large intestines. At this time the outgrowth is of the same size throughout, and is practically equal to the intestines in diameter. About the eleventh week, whilst the large and small bowels are still of the same width, it has increased very considerably in length (being equal to about five times the diameter of the small intestine, and thus being relatively as long as in the adult); but even at this early date the basal portion, for about one-fifth of its length, is quite as wide as the intestine, whilst the remaining four-fifths of the outgrowth—the future appendix—is only about one-half or one-third the diameter of the gut. From this it is seen that the distal portion of the outgrowth, which subsequently becomes the vermiform process, begins to lag behind even at this early period of its development.

The basal portion continues to expand with the gut; the distal part grows rapidly enough in length, but otherwise enlarges very slowly, so that, towards the end of fœtal life, the cæcum has attained a conical shape, the wider end joining the ascending colon, the narrow end tapering gradually and passing into the vermiform process. This form, known as the infantile type of cæcum, is retained for some time after birth, or even may (in 2 or 3 per cent of cases) persist throughout life.

As early as the sixth or seventh month of fœtal life the wall of the terminal portion of the small intestine adheres to the inner side of the cæcum for some distance below the ileo-cæcal orifice. And this connexion, which is rendered more intimate by the passage of two folds of peritoneum, one on the front, the other on the back, between the two parts, profoundly modifies the subsequent growth of the cæcum, and determines very largely its adult form. For, when the cæcum begins to expand, the inner aspect is prevented, by its connexion with the termination of the ileum, from enlarging as freely as the rest of the wall; in consequence of this the outer part grows and expands much more rapidly, producing the lop-sided appearance already referred to, and soon comes to form the lowest part or fundus of the cæcum, and the greater part of its sac; whilst the original apex, with the vermiform appendix springing from it, anchored, as it were, to the end of the ileum, is thrust to one side, and finally lies on the inner and posterior aspect of the cæcum, a little way below, and usually posterior to, the end of the ileum.

The position of the cæcum varies at different periods of fœtal life. About the eleventh or twelfth week it lies immediately beneath the liver, and to the left of the middle line; it then gradually travels to the right, crossing the descending duodenum, and is found lying on the right side, just beneath the liver, at the fourth month. From this it descends slowly to its adult position, which it usually approaches towards the end of fœtal life, but it may not actually reach it until some time after birth. An imperfect descent gives rise to the lumbar position of the cæcum, or an excess in this direction to the pelvic position (referred to on p. 1076).

**Types of Cæcum.**—Three chief types of cæcum may be distinguished—the *fœtal type*, conical in shape and nearly symmetrical, with the lower end gradually passing into the vermiform

appendix; the *infantile*, in which the passage from the cæcum to the vermiform process becomes more abrupt, the outer wall more prominent, and the whole sac more unsymmetrical; and the lop-sided *adult form*, as described above, which is the condition found in 93 or 94 per cent of adults.

**Structure.**—Nothing in the arrangement of the mucous and submucous coats calls for special notice. The tæniæ or longitudinal bands of the muscular coat all spring from the base of the vermiform appendix (Fig. 766); the anterior runs up on the front, internal to the main prominence of the cæcum; the postero-external runs up behind this prominence; whilst the postero-internal passes directly upwards behind the ileum (Fig. 766). The longitudinal fibres on the upper aspect of the ileum partly join the postero-internal tænia; those on the front and back join the circular fibres of the large gut.

The serous coat has, in connexion with it, certain folds and fossæ which are described at p. 1081.

**Vermiform Process or Appendix Cæci** (Fig. 768).—The appendix is a worm-like tubular outgrowth which springs from the inner and back part of the cæcum about 1 to 1½ inches (2·5 to 3·75 cm.) below the ileo-cæcal orifice. From this it generally runs in one of three chief directions, namely—(1) over the brim, into the pelvis; (2) upwards behind the cæcum; or (3) upwards and inwards, thus pointing

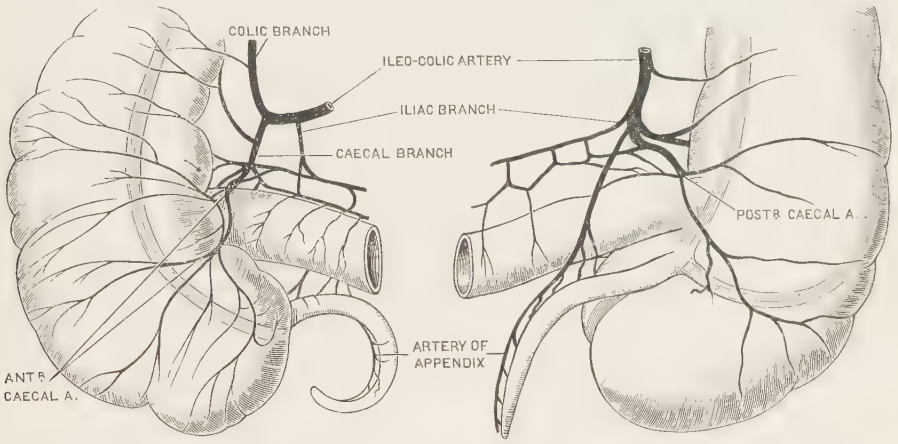

FIG. 766.—THE BLOOD SUPPLY OF THE CÆCUM AND VERMIFORM APPENDIX.

The illustration to the left gives a front view, in that to the right the cæcum is viewed from behind. In the latter the artery of the appendix, and three tæniæ coli springing from the base of the appendix, should be specially noted (modified from Jonnesco).

towards the spleen; each of which has been considered to be the normal position by one or more observers. In the first of these situations it is quite evident as it hangs over the pelvic brim; in order to expose it in the second, the cæcum must be turned upwards; whilst, in the third position, it lies behind the end of the ileum and its mesentery, and these must be raised up in order to display it. In addition to the positions just mentioned, it has been found in almost every possible situation in the abdomen which its length and the extent of its mesentery would allow it to attain. In every case the anterior tænia of the cæcum, which is always distinct, offers the surest guide to the process, the base of which can be located with certainty by following this tænia to the back of the cæcum (Fig. 766).

Its size is almost as variable as its position. Taking the average of numerous measurements, its length may be given as about 3½ inches (92 mm., Berry), and its breadth as ¼ inch (6 mm., Berry). On the other hand, it has been found as long as 9 inches (230 mm.), and as short as ¾ inch (18 mm.). Even its absence has been recorded (Fawcett).

Its *lumen* or *cavity* is variable in its development, and is found to be totally or partially occluded in at least one-fourth of all adult and old bodies examined. This is looked upon as a sign of degeneracy in the process, which is by many considered to be undergoing a gradual obliteration in the human species. It opens into the cavity of the cæcum on its inner, or inner and posterior aspect (Fig. 763), at a point 1 to 1½ inches (2·5 to 3·8 cm.) below, and somewhat behind

the ileo-cæcal orifice. These are the relative positions of the two orifices, as seen from the interior of the cæcum; viewed from the exterior, the base of the appendix is within $\frac{3}{4}$ inch of the lower border of the ileum. This apparent difference is due to the fact that the ileum adheres to the inner side of the cæcum for a distance of nearly 1 inch before it opens into it.

Sometimes the orifice of the appendix has a crescentic fold or valve (valvula processus vermiformis) placed at its upper border; but it is probably of very little functional importance when present, for the aperture of the appendix is usually so small that its cavity is not likely to be invaded by the contents of the cæcum.

The vermiform process is completely covered by peritoneum, and has a considerable mesentery, the *meso-appendix* (mesenteriolum processus vermiformis), which extends to its tip as a rule, and connects the process to the under surface of that part of the mesentery proper which goes to the lower end of the ileum.

The appendix is relatively, to the rest of the large intestine, longer in the child at birth than in the adult, the proportion being about 1 to 16 or 17 at birth and 1 to 19 or 20 in the adult. (The difference is certainly not as great as stated by Ribbert, who makes the proportion 1 to 10 at birth and 1 to 20 in the adult.) The process attains its greatest length and diameter during adult and middle age, and atrophies slowly after that time. It is said to be slightly longer in the male than in the female.

Total occlusion of its cavity is found in 3 or 4 per cent of bodies; it is then converted into a fibrous cord. Partial occlusion is present in 25 per cent of all cases, and in more than 50 per cent of those over 60 years old, whilst it is unknown in the child. This frequency of occlusion, the physiological atrophy which takes place after middle life, the great variations in length, and other signs of instability, have been considered to point to the retrogressive character of the appendix.

A vermiform process is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the cæcum is very slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous cæcum, which has been replaced by the carnivorous form. Another and perhaps more probable view regards the appendix as a lymphoid organ, having the same functions as Peyer's patches, and like these undergoing degeneration after middle life (Berry).

In the fœtus and child, as well as in the adult with the infantile type of cæcum, the appendix springs from the true apex, not from the inner and posterior aspect.

Foreign bodies, although reputed to find their way very easily into the appendix, are rarely found there after death. On the other hand, concretions or calculi, formed of mucus, fæces, and various salts, are often present (Berry).

**Structure** (Fig. 767).—The **serous coat** is complete, and forms a perfect investment for the process. The **muscular coat**, unlike that of the rest of the large intestine, has a

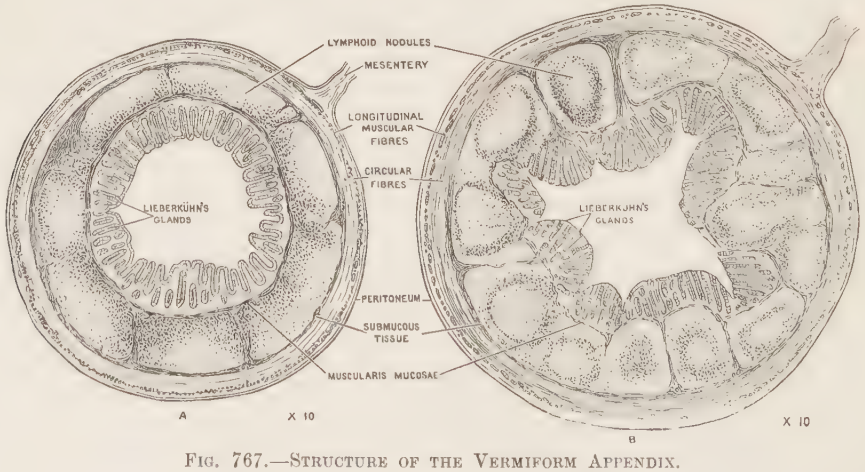

Fig. 767.—Structure of the Vermiform Appendix.

A. From a child two years old. B. From a male, age 56.

It will be observed that the submucosa is almost entirely occupied by lymphoid nodules and patches. The muscularis mucosæ is very faint, and lies quite close to the bases of Lieberkühn's glands. The longitudinal layer of muscular fibres forms a continuous sheet.

continuous and stout layer of longitudinal fibres, which passes at the root of the process into the three tæniæ coli (Fig. 768). The layer of circular fibres is well developed. The **submucosa** is almost entirely occupied by large masses of lymphoid tissue surrounded by

sinus-like lymph spaces. Owing to the large size of these lymphoid nodules, the areolar tissue of the submucosa is compressed against the inner surface of the muscular coat, and forms a well-marked fibrous ring, which sends processes at intervals between the lymphoid masses towards the mucous membrane. The inner portion of this fibrous ring seems to have been generally mistaken for the muscularis mucosæ, which latter, as seen in Fig. 767, lies internal to the chief masses of lymphoid tissue, and not outside it, as figured by Testut. These lymphoid nodules, which correspond to solitary glands, have, owing to their great number, been almost completely crushed out of the mucosa (in which they chiefly lie in the intestine) into the submucosa.

The **mucous coat** corresponds to that of the large intestine in its general characters, but the Lieberkühn's glands are fewer, and irregular in their direction; the muscularis mucosæ is thin and ill-defined; it lies just internal to the lymphoid nodules of the submucosa, and immediately outside the base of Lieberkühn's glands. Some few lymphoid nodules lie in the mucous coat also.

**Blood-vessels of the Cæcum and Vermiform Appendix** (Fig. 766).—These parts are supplied with blood by the **ileo-cæcal artery.** This gives off, near the upper angle formed by the junction of the ileum with the small intestine—(*a*) an *anterior cæcal artery*, which passes down on the front of the ileo-cæcal junction to the cæcum, and breaks up into numerous branches for the supply of that part; (*b*) a *posterior cæcal artery*, similarly disposed on the back; and (*c*) the *artery of the appendix.* The last-named branch passes down behind the ileum (Fig. 766), then enters the mesentery of the appendix, and running along this near its free border, sends off several branches across the little mesentery to the appendix, before finally ending in it. The course of the artery behind the ileum is said to render it subject to pressure from fæcal masses in that gut, and thus to predispose to an interference with the supply of the appendix, and morbid changes in the process. It has also been said that the appendix receives a small branch from the left ovarian artery in the female—a statement which I have been unable to verify.

The **veins** correspond to the arteries. The **lymphatics** pass with the vessels to join a few small glands which are found in the mesentery of the appendix at its base, the efferent vessels from which join the mesocolic glands behind the ascending colon.

**Cæcal Folds and Fossæ.**—The peritoneum forms in the neighbourhood of the cæcum certain fossæ, of which the most interesting and important are—(*a*) the retro-cæcal or retro-colic fossæ; (*b*) the ileo-cæcal fossa; and (*c*) the ileo-colic fossa.

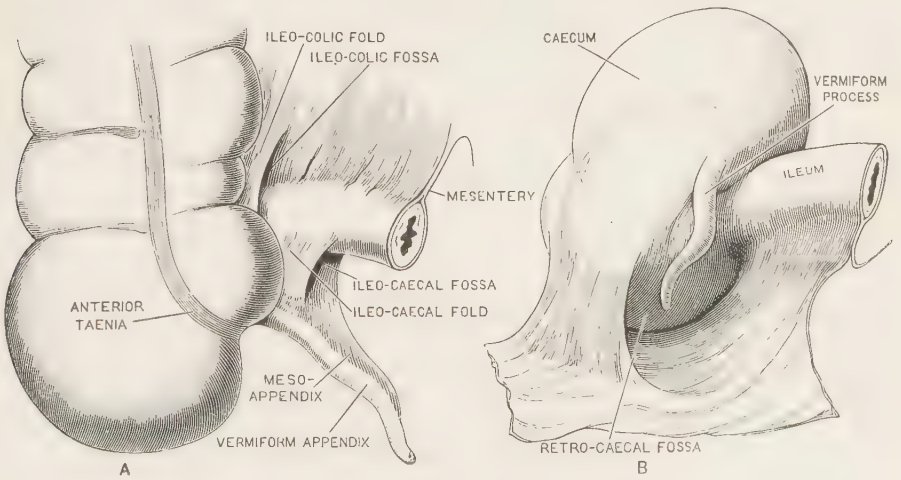

FIG. 768.—THE CÆCAL FOLDS AND FOSSÆ.

In A, the cæcum is viewed from the front; the mesentery of the appendix is distinct, and is attached above to the under surface of the portion of the mesentery going to the end of the ileum. In B, the cæcum is turned upwards to show a retro-cæcal fossa, which lies behind it and the beginning of the ascending colon.

The **retro-colic fossæ** (Fig. 768, B) are only occasionally present, and are exposed by turning the cæcum and adjacent part of the ileum upwards. Two forms, external and internal, are described; the first lies behind the outer part of the ascending colon, immediately above the cæcum; the second behind its inner part. These fossæ are specially interesting because, when present, they frequently lodge in the vermiform process (see Fig. 768, B), a condition which is said to favour the production of appendicitis.

**Ileo-cæcal Fossa and Fold.**—If the appendix be drawn down, and the finger run

towards the cæcum, along the *lower* border of the terminal part of the ileum, its point will generally run into a fossa situated in the angle between the ileum and cæcum (Fig. 768, A), which is known as the ileo-cæcal fossa. The fold which bounds the fossa in front is the ileo-cæcal fold (the "bloodless fold of Treves"). It passes from the ileum to the front of the meso-appendix, which latter forms the posterior wall of the fossa.

**Ileo-colic Fold and Fossa.**—Similarly, if the finger be run out along the *upper* border of the ileum towards the cæcum, it will usually lodge in a smaller fossa, the ileo-colic, which is bounded in front by a small peritoneal process, the ileo-colic fold (Fig. 768, A), containing the anterior cæcal artery.

## THE COLON.

**Ascending Colon** (colon ascendens).—This section of the great gut begins about the level of the intertubercular plane, opposite the ileo-cæcal orifice, where it is continuous with the cæcum. From this it runs upwards and somewhat backwards, with a slight concavity to the left, until it reaches the under surface of the liver, where it bends forwards and to the left, and passes into the hepatic flexure (Fig. 769). In its course it lies in the angle between the quadratus lumborum behind, and the more prominent psoas internally (Fig. 742).

It is situated chiefly in the right lumbar region, but it extends slightly into the hypochondrium above; and, although it usually begins about the level of the intertubercular line, still with a low position of the cæcum it will extend further down, and may occupy a considerable part of the iliac region.

Its *length* is about 8 inches (20 cm.), and it is wider and more prominent than the descending colon. It generally presents several minor curves or flexures, and it often has the appearance of being pushed into a space which is too short to accommodate it.

**Relations.**—*In front*, it is usually in contact with the abdominal wall, but the small intestine frequently intervenes, particularly above (Fig. 739). To its *inner side* lie the coils of the small bowel and the psoas; to the *outer side* is the lateral wall of the abdomen. Its *posterior surface*, which is free from peritoneum as a rule (Fig. 742), is connected by areolar tissue to the iliacus muscle as far up as the crest of the ilium, to the quadratus lumborum above this, and finally to the lower and outer part of the right kidney.

In the great majority of cases only the two sides and the anterior surface are covered by peritoneum, the posterior surface being destitute of a serous coat (Fig. 742). In a small proportion of bodies, however, the ascending colon is provided with a complete peritoneal coat and a mesentery, but this latter is so short that it admits of but a slight amount of movement in the gut.

Like the cæcum, the ascending colon is frequently found distended with gas or fæces after death, hence in part its large size and prominence as compared with the descending colon, which is generally empty.

**Hepatic Flexure** (flexura coli dextra). The hepatic flexure is the bent piece of the large intestine between the end of the ascending colon and the beginning of the transverse colon (Figs. 758 and 769).

When the ascending colon, lying on the front of the kidney, reaches the under surface of the liver, it bends—usually acutely, sometimes obtusely—forwards and to the left, and on reaching the front of the descending duodenum, passes into the transverse colon.

The flexure is placed between the descending duodenum internally and the lower thin margin of the liver, or the lateral abdominal wall, externally; above, it corresponds to the colic impression on the liver, and behind it rests on the kidney. Its peritoneal relations are similar to those of the ascending colon.

**Transverse Colon** (colon transversum).—This is the long and arched portion of the large intestine which lies between the hepatic and splenic flexures. It begins where the colon crosses the descending duodenum at the end of the hepatic flexure (Fig. 769). From this it runs transversely to the left, and for the first few inches is comparatively fixed, being united to the front of the descending duodenum and the head of the pancreas either by a very short mesentery or by areolar tissue. Immediately beyond this a long mesentery is developed, which allows the

colon to hang down in front of the small intestine, at a considerable distance from the posterior abdominal wall. Towards its left extremity the mesentery shortens again, thus bringing the gut towards the tail of the pancreas (Fig. 758), along which it runs upwards into the left hypochondrium, under cover of the stomach, as far as the lower end of the spleen, where it passes into the splenic flexure (Fig. 757). Its two ends lie in the right and left hypochondriac regions respectively, whilst its middle portion hangs down into the umbilical, or even the hypogastric region.

Its average *length* is about 19 or 20 inches (47·5 to 50·0 cm.), that is more than twice the distance, in a direct line, between its two extremities. This great length is accounted for by the curved and somewhat irregular course which the bowel pursues.

**Relations.**—The greater part of the transverse colon lies behind the great omentum, which must consequently be turned upwards in order to expose it. *Above*, it is in contact, from right to left (Fig. 769), with the liver and gall-bladder, the stomach, and, near its left end, with the tail of the pancreas and lower end of the spleen (Fig. 758). *In front* are placed the omentum and the anterior abdominal wall; towards its termination the stomach is likewise in front. *Behind*, it first lies in contact with the descending duodenum and head of the pancreas; beyond this, where it hangs down, the small intestine is placed below and behind, and it is connected to the posterior abdominal wall (more correctly, to the anterior border of the pancreas) by the transverse mesocolon. It is also loosely connected to the stomach by the great omentum, which is attached to its anterior surface. The transverse mesocolon and the great omentum are described with the peritoneum, p. 1097.

The transverse colon is completely covered by peritoneum, with the exception of the first few inches of its posterior surface, which are often, if not usually, uncovered.

The state of the peritoneal covering on the back of the first part of the transverse colon would seem to depend, in some degree, on the extent to which the liver passes downwards on the right side. With a small high liver no mesentery is present, and the posterior surface is devoid of peritoneum; on the other hand, when the liver is enlarged in the vertical direction, it pushes the colon downwards before it, and brings the upper line of the peritoneal reflection from its back, into contact with the lower, thus giving rise to the mesentery. In the fœtus of three or four months every part of the colon is supplied with a long mesentery; subsequently this, as a rule, disappears at the beginning of the transverse colon, but it may be reproduced in the manner stated.

**Splenic Flexure** (flexura coli sinistra).—The terminal portion of the transverse colon runs upwards (also backwards and to the left) until the lower end or base of the spleen is reached; here it bends sharply, forming the splenic flexure, and runs down into the descending colon. The flexure is placed deeply in the left hypochondrium, behind the stomach, and in contact with the base of the spleen. It lies at a higher level than the hepatic flexure, and is connected to the abdominal parietes by the phreno-colic ligament, which helps to maintain it in this position.

**Phreno-colic or Costo-colic Ligament** (ligamentum phrenocolicum, Fig. 758).—This is a triangular fold of peritoneum, with a free anterior border, which is attached internally to the splenic flexure and externally to the diaphragm opposite the eleventh rib. Owing to the fact that the base of the spleen rests upon it, the ligament has also received the name of **sustentaculum lienis.**

The phreno-colic ligament is formed in the fœtus from the left margin of the great omentum (Jonnesco and Fig. 758).

The peritoneal covering of the splenic flexure is similar to that of the descending colon.

**Descending Colon** (colon descendens).—This is much narrower and less obtrusive than the ascending colon: indeed in a large number of cases it is found firmly contracted. It begins in the left hypochondrium at the splenic flexure, passes down on the left side of the abdomen, and ends in the lumbar region, opposite the crest of the ilium, by passing into the iliac colon. Its course is not quite straight, for it first curves downwards and inwards along the outer side of the left kidney, and then descends almost vertically to the iliac crest (Fig. 769).

Its *length* is usually from 4 to 6 inches (10 to 15 cm.), and its *width*, which is less than that of the ascending colon, about 1½ inches (37 mm.).

**Relations.**—The descending colon first lies in contact with the outer aspect of the left kidney; below this it is placed, like the colon of the opposite side, in the angle between the psoas and quadratus lumborum muscles. *Behind*, it rests upon the lower part of the diaphragm above, and on the quadratus lumborum below. *In front* (and somewhat to the outer side also, except when the bowel is distended) are placed numerous coils of small intestine, which hide the colon completely from

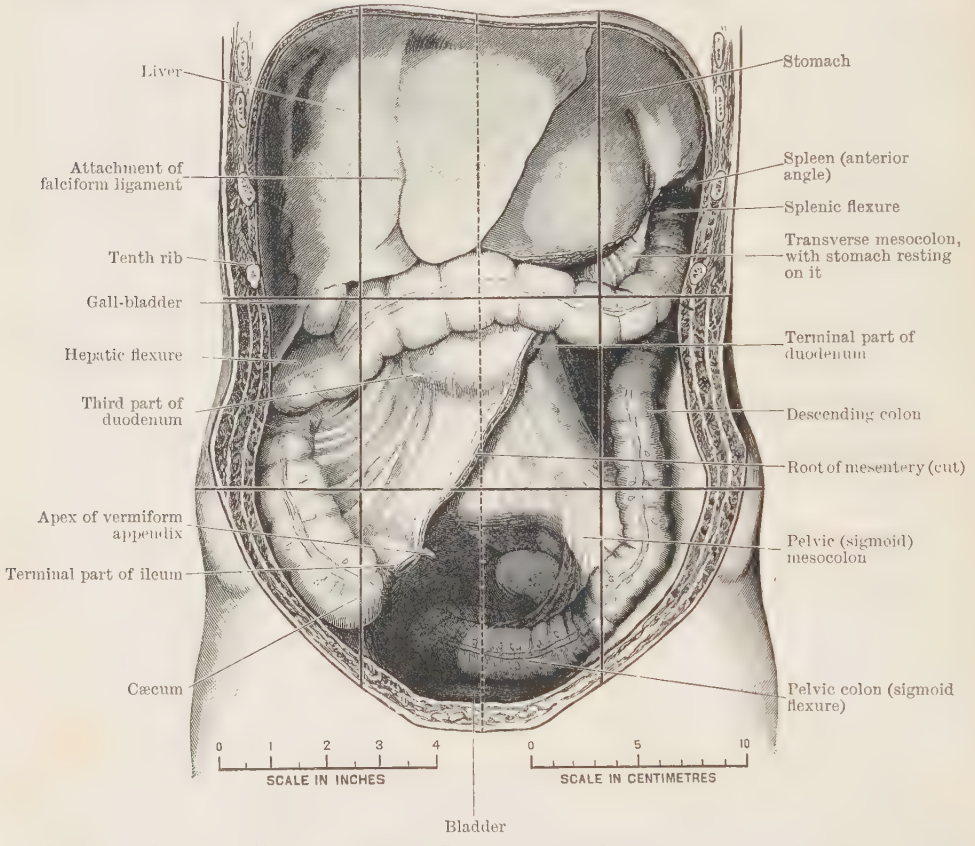

Fig. 769.—The Abdominal Viscera after the Removal of the Jejunum and Ileum (from a photograph of the same body as depicted in Fig. 739). The transverse colon is much more regular than usual. Both the liver and cæcum extend lower down than normal. The subdivisions of the abdominal cavity are indicated by dark lines.

view, and compress it against the posterior abdominal wall. To its *inner side* lies the lower part of the kidney above, the psoas below.

In the great majority of bodies only the front and sides of the descending colon are covered by peritoneum (Fig. 779); the posterior surface, being destitute of a serous coat, is connected to the posterior wall of the abdomen by areolar tissue. In a small proportion of cases, on the other hand, the serous coat is complete, and the colon is furnished with a short mesentery.

Up to the fourth or fifth month of fœtal life the descending colon has a complete investment of peritoneum and a long mesentery. After the fifth month the mesentery adheres to, and soon blends with, the parietal peritoneum on the posterior abdominal wall, and is completely lost as a rule. The persistence of this mesentery, in a greater or less degree, explains the occasional presence of a descending mesocolon in the adult.

**Sigmoid Flexure and Rectum.**—It was formerly customary to divide the remaining portion of the large intestine into sigmoid flexure and rectum. The former was said to begin at the crest of the ilium, to lie in the iliac fossa, and to end at the brim of the pelvis. Or, in later years, the "sigmoid colon" was described as "that part of the colon which is attached to the left iliac fossa, from the iliac crest to the brim of the true pelvis" (Symington). Its upper part was said to be covered by peritoneum on the anterior and lateral surfaces only, its lower part

to form a large loop with a complete serous coat and a long mesentery, which hung down into the pelvic cavity when the bladder and rectum were empty, and passed up out of it when these were distended.

The rectum was described as beginning at the brim of the pelvis, opposite the left sacro-iliac joint, and as ending at the anus. It was divided into three portions, of which the first extended from the brim of the pelvis to the middle of the third piece of the sacrum, had a complete covering of peritoneum, and was connected to the pelvic wall by a mesentery—the mesorectum. The second and third parts of the rectum we may pass over for the present, as they agree in general with the description of the rectum given below.

Treves in 1885, and Jonnesco in 1889, directed attention to the fact that no such loop as the classical sigmoid flexure, lying in the iliac fossa, was to be found in nature; and also, that the separation of the first portion of the rectum from the sigmoid flexure—so-called—was both artificial and inaccurate. They pointed out that the "first part of the rectum" really belongs to the sigmoid flexure, with which it has everything in common, and that on no grounds could it be properly assigned to the rectum.

An unbiassed study of the parts concerned, particularly in bodies the viscera of which have been hardened *in situ*, will leave little doubt on an unprejudiced mind that the old descriptions are not only artificial but erroneous. Consequently, the admirable account of this part of the intestine, given by Jonnesco, will be followed in its main features in describing the divisions of the bowel heretofore known as the sigmoid flexure and first part of the rectum.

Jonnesco, recognising that this portion of the intestine lies partly in the iliac fossa and partly in the pelvis, very appropriately calls the former the iliac colon and the later the pelvic colon. The **iliac colon** includes the portion of the "sigmoid flexure" which extends from the crest of the ilium to the inner side of the psoas muscle (that is practically the brim of the pelvis), and is usually destitute of a mesentery. The **pelvic colon** embraces the remainder of the "sigmoid colon" and the first part of the rectum, both of which are attached by a continuous mesentery, and form one large loop lying in the pelvic cavity, and ending at the level of the third sacral vertebra by passing into the **rectum proper**.

**Iliac Colon** (colon iliacum).—This corresponds to the portion of the "sigmoid flexure" which lies in the iliac fossa, and it has no mesentery. It is the direct continuation of the descending colon, with which it agrees in every detail, except as regards its relations. Beginning at the crest of the ilium, it passes downwards and somewhat inwards, lying in front of the iliacus muscle. A little way above Poupart's ligament it turns inwards over the psoas, and ends at the inner border of this muscle by dipping into the pelvis and becoming the pelvic colon (Fig 769). It usually measures about 5 or 6 inches (12·5 to 15 cm.) in length, but it varies considerably in this respect.

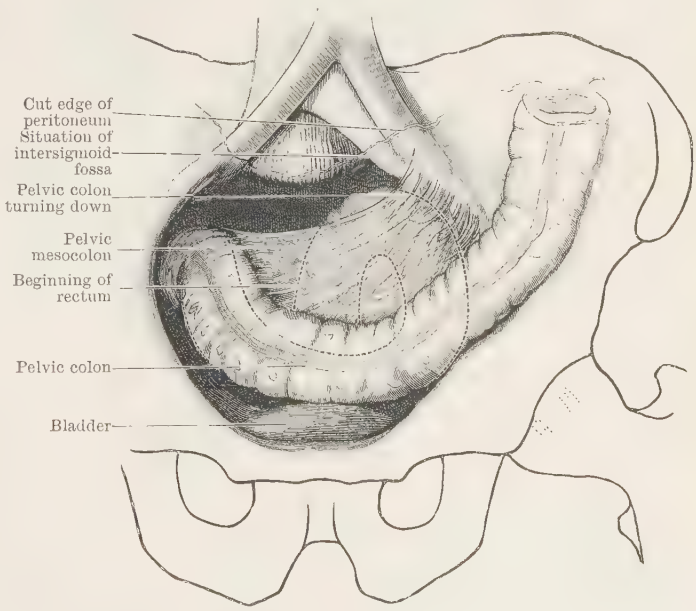

FIG. 770.—THE ILIAC AND PELVIC COLONS, from a formalin-hardened male body, aged 30.

The pelvic colon was unusually long; its course is shown, as well as that of the beginning of the rectum, by dotted lines. It first runs across the upper surface of bladder to the right pelvic wall, then recrosses the pelvis in a line posterior to its first crossing; finally it returns towards the middle line, and passes into the rectum. As a rule, after crossing to the right side of the pelvis, the pelvic colon turns backwards and inwards to reach the middle line, where it passes into the rectum.

**Relations.** — *Behind,* it lies upon, and, as a rule, is connected by areolar tissue to, the front of the ilio-psoas muscle. *In front,* it is usually covered by coils of small intestine, which hide it from view; but when distended, or when it occupies a lower position than usual, it comes into direct contact with the anterior abdominal wall. As a rule (90 per cent of bodies—Jonnesco), it is covered by peritoneum only

on its anterior and two lateral surfaces. Occasionally (10 per cent of cases) it is completely covered, has a short mesentery (1 inch, 2 to 3 cm.), and is slightly movable.

In its course it passes down over the iliac fossa near its middle, generally forming a curve with its concavity directed inwards and upwards, and having reached a point 1½ or 2 inches (4 to 5 cm.) above Poupart's ligament, it turns inwards across the psoas towards the pelvic cavity. Occasionally the iliac colon occupies a lower position than usual, and runs along the deep surface of Poupart's ligament, immediately behind the anterior abdominal wall.

**Pelvic Colon** (colon pelvinum). — This corresponds to the portion of the "sigmoid flexure" which lies in the pelvis, together with the so-called "first part of the rectum." The pelvic colon is a large coil of intestine, which begins at the inner border of the left psoas muscle, where it is continuous with the iliac colon, and ends at the level of the third sacral vertebra by passing into the rectum proper. Between these two points it has a well-developed mesentery, and forms a large and variously-shaped coil, which usually lies in the cavity of the pelvis (93 per cent).

Whilst the loop of the pelvic colon is very irregular in form, the following may be given as perhaps its most common arrangement. Beginning at the inner margin of the left psoas, it first plunges over the brim into the pelvis, and crosses this cavity from left to right; it next bends backwards and then returns along the posterior wall of the pelvis towards the middle line, where it turns down and passes into the rectum (Figs. 769 and 770).

**Relations.**—In its passage into the pelvis it crosses the external iliac vessels; in running from left to right across the cavity, it rests on the bladder or uterus, according to the sex; whilst above it lie the coils of the small intestine.

It is completely covered by peritoneum, and is furnished with an extensive mesentery—the pelvic mesocolon—which permits of considerable movement.

Sometimes, when longer than usual (Fig. 770), the pelvic colon, in returning from the right side of the pelvis, crosses the middle line, going even as far as the left wall, and then turns back a second time towards the middle of the sacrum, where it joins the rectum at the usual level, thus making an S-shaped curve within the pelvis. On the other hand, when the loop is short (a not infrequent occurrence), all its curves are abridged, and it fails to pass over to the right side, but runs more or less directly backwards after entering the pelvis.

From what has been said it will be seen that the loop of the pelvic colon is subject to numerous and considerable variations, which are chiefly dependent upon its length and that of its mesentery, and also upon the state of emptiness or distension of itself and of the other pelvic viscera. When the intestine is long the loop is more complex; when short, more simple. When the bladder and rectum are distended, or when the pelvic colon itself is much distended, it is unable to find accommodation in the true pelvis, and consequently it passes up into the abdominal cavity, almost any part of the lower half of which it may occupy. But, as already stated, in the great majority of cases (92 per cent, according to Jonnesco) it is found after death lying entirely within the pelvic cavity.

In *length*, the pelvic colon generally measures about 16 or 17 inches (40 to 42·5 cm.), but it may be as short as 5 inches (12 cm.), or as long as 35 inches (84 cm.).

The **pelvic mesocolon**, which corresponds to both the sigmoid mesocolon and the mesorectum, is a fan-shaped fold, short at each extremity, and long in its middle portion (Figs. 769 and 770). Its root is attached along an inverted V-shaped line, one limb of which runs up close to the inner border of the left psoas, as high as the bifurcation of the common iliac artery (or often higher); here it bends at an acute angle, and the second limb descends over the sacral promontory and along the front of the sacrum to the middle of its third piece, where the mesentery ceases, and the pelvic colon passes into the rectum. When the pelvic colon ascends into the abdominal cavity this mesentery is doubled up on itself, the side which was naturally posterior becoming anterior.

**Intersigmoid Fossa** (recessus intersigmoideus).—When the pelvic colon with its mesentery is raised upwards, a small orifice will usually be found beneath the mesentery, corresponding to the apex of the V-shaped attachment of its root to the posterior abdominal wall. This orifice leads into a fossa which is directed upwards, and will often admit the last joint of the little finger. It is known as the *intersigmoid fossa*, and is due to the imperfect blending of the mesentery of the descending colon of the fœtus with the parietal peritoneum. In the fœtus this mesentery is well developed, and extends from the region of the vertebral column out towards the descending colon. After a time it begins to unite with the underlying parietal peritoneum; but in the region of the intersigmoid fossa the union is rarely perfect, hence the presence of the fossa.

In the **child at birth** only the terminal part of the pelvic colon lies in the pelvis. This is chiefly owing to the small size of the pelvic cavity in the infant. Beginning at the end of the iliac colon, the pelvic colon generally arches upwards and to the right across the

abdomen towards the right iliac fossa, where it forms one or two coils, and then passes down over the right side of the pelvic brim into the pelvic cavity. In cases of imperforate anus, it is important to remember, in connexion with the operation for forming an artificial anus, that, whilst the iliac colon is found in the left iliac region, the pelvic colon ("sigmoid flexure") usually lies on the right side, and passes over the right portion of the brim to enter the pelvis.

**Structure of the Pelvic Colon.**—Only the arrangement of the muscular coat need be referred to. As the tæniæ of the descending colon are followed down, it will be found that the postero-external band gradually passes on to the front, and unites with the anterior tænia to form a broad band, which occupies nearly the whole width of this bowel in its lower portion. The postero-internal tænia spreads out in a similar manner on the back; so that in the lower half of the pelvic colon the longitudinal layer of the muscular coat is complete, with the exception of a narrow part on each side; here the circular fibres come to the surface, and the intestine presents a series of small sacculations. These, however, disappear, and the longitudinal fibres, although thicker in front and behind, form a continuous layer all round, as the rectum proper is approached.

## THE RECTUM.

The **rectum** (proper intestinum rectum: second portion of the rectum according to the older method of description) is the comparatively dilated portion of the large bowel which intervenes between the pelvic colon above and the anal canal—the

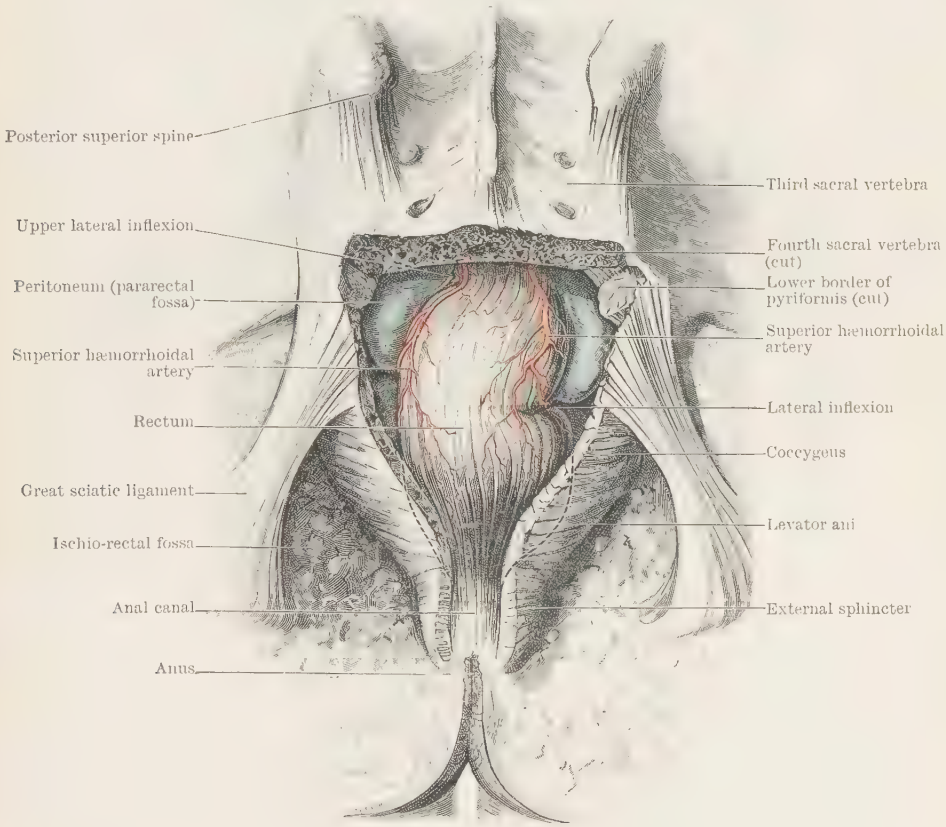

FIG. 771.—THE RECTUM FROM BEHIND.

The sacrum has been sawn across through the 4th sacral vertebra, and its lower part removed with the coccyx. The posterior portions of the coccygei, levatores ani, and of the external sphincter have been cut away. The "pinching in" of the lower end of the rectum by the inner edges of the levatores ani, resulting in the formation of the flattened anal canal, is suggested in the illustration, which has been made from a formalin-hardened male body, aged thirty. The lateral inflexions of the rectum, corresponding to Houston's valves, are also shown.

slit-like passage through which it communicates with the exterior (Fig. 771). It forms a temporary reservoir in which the fæces accumulate a short time before they are discharged from the body, but as a result of habit this temporary function may be converted into a more or less permanent one.

Unlike the portion of the bowel which immediately precedes it, the rectum has but a partial covering of peritoneum, and is entirely destitute of a mesentery;

sacculations, too, which are so characteristic of the large intestine, cannot properly be said to be present.

The rectum begins at the termination of the pelvic mesocolon, namely, about the level of the third sacral vertebra, and ends, where the bowel pierces the pelvic floor, opposite the lower and back part of the prostate in the male, or at a point $1\frac{1}{2}$ inches (3·7 cm.) in front of, but at a lower level than, the tip of the coccyx in both sexes. It first descends along the front of the sacrum and coccyx, following the curve of these bones; beyond the coccyx, it rests, for about $1\frac{1}{2}$ inches (3·7 cm.), on the back part of the pelvic floor, here formed by the union of the two levatores ani; and finally, having reached the lower part of the prostate, it bends rather abruptly

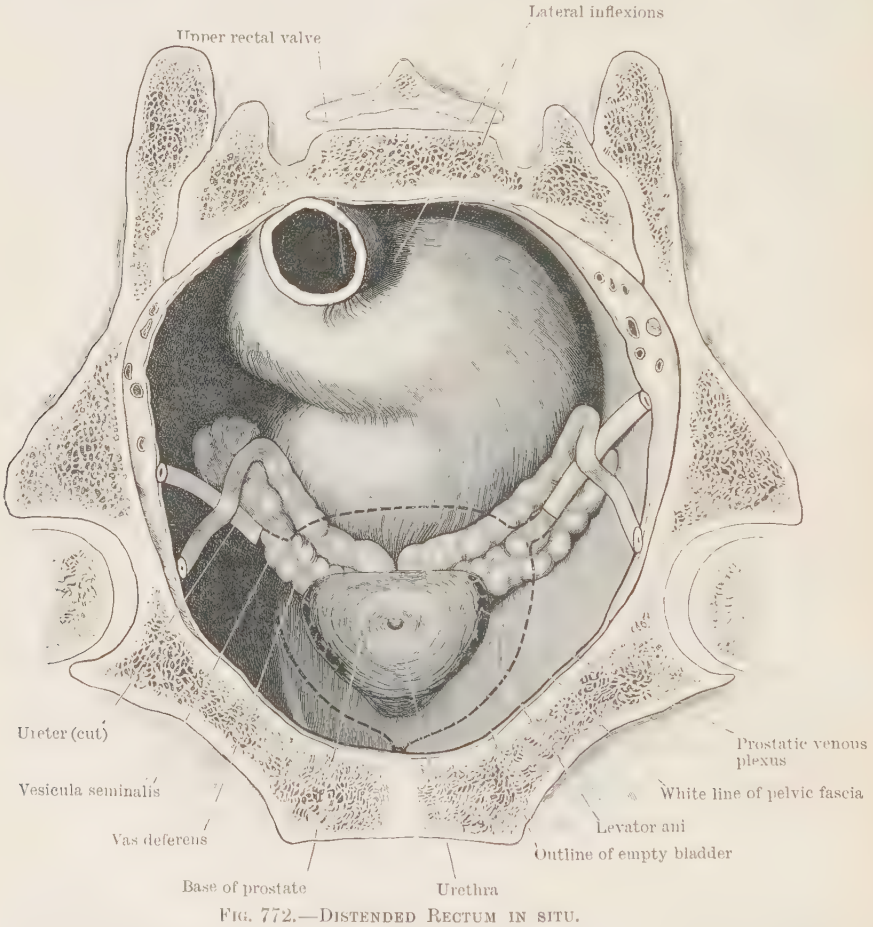

FIG. 772.—DISTENDED RECTUM IN SITU.

From a formalin-hardened male body, age 56. The peritoneum and extra-peritoneal tissue have been removed, after sawing the pelvis along a plane passing through the upper part of the symphysis pubis in front and the lower part of the second sacral vertebra behind. The bladder, which was empty and contracted, has also been removed, but its form is shown by a dotted line. The rectum was very much distended, and almost completely occupied the pararectal fossæ.

backwards and downwards, and, piercing the pelvic floor, passes into the anal canal (Fig. 774).

Its general direction is downwards, but this varies at its two extremities, being downwards and backwards above, downwards and strongly forwards below.

**Curvatures.**—The rectum is far from straight, notwithstanding its name, which describes its condition fairly accurately in most animals, but not in man, in whom it is curved in both the antero-posterior and the transverse planes. Viewed *from the side*, it forms a gentle curve, with the convexity backwards, which extends from the beginning of the rectum to the back of the prostate, and fits into the hollow of the sacrum and coccyx. At the back of the prostate a second curve is formed where the rectum joins the anal canal; this

has its convexity directed forwards, whilst its concavity embraces the **ano-coccygeal body**—the mass of muscular and connective tissue which lies between the tip of the coccyx and the anal canal.

When *viewed from the front* the rectum is seen to be regularly folded from side to side in a zigzag fashion, the folding being slightly marked when the rectum is empty, but becoming much more distinct with distension (Figs. 772 and 773). In other words, when viewed from this aspect it presents, in the majority of cases, three more or less distinct lateral flexures or inflexions. Of these the upper and lower have their concavities directed to the left as a rule; the third flexure, which is the best marked, lies between the other two, but on the right side. Not infrequently, however, two are found on the right and one on the left side. The flexures, which are marked on the exterior by a crease, appear in the interior as three prominent crescentic shelves (Fig. 774), known as the **rectal valves**, which help to support the fæcal contents when the rectum is distended (Fig. 772).

This folding is maintained by the arrangement of the longitudinal muscular fibres, the majority of which are accumulated in the form of two wide bands, one on the front, the other on the back of the bowel. These two bands, which are continuous with, and comparable in their functions to, the tæniæ of the colon, are shorter than the other coats of the rectum; hence they give rise, as in the case of the colon, to a folding or sacculation of the tube, which can be effective only at the sides where the longitudinal fibres are fewest, for the front and back are occupied by the thickened longitudinal bands (see p. 1092).

In addition to supporting the fæces, these foldings greatly increase the capacity of the rectum without unduly dilating the tube. When the rectum is empty (Fig. 773) its course is comparatively straight, its lateral flexure being but slightly marked, and its whole calibre very much reduced. In this condition it occupies only a small portion of the posterior division of the pelvic cavity near the mesial plane, and at each side, between it and the lateral wall of the pelvis, is a large fossa of the peritoneum (the pararectal fossa, p. 1101), which, when the bowel is empty, contains a mass of small intestine or pelvic colon (Figs. 771 and 773). When the rectum is distended the lateral flexures become much more marked, and the gut, projecting alternately to each side, passes out beneath the peritoneum, obliterating the pararectal fossæ (Fig. 772), and fills the greater part of the posterior division of the pelvis—a condition which could not be brought about with a straight rectum without an enormous increase in all the diameters of the tube.

According to Jonnesco, the rectum begins—that is, the pelvic mesocolon ceases—most frequently opposite the disc between the third and fourth sacral vertebræ. It is our experience that the mesocolon ends more frequently above than below the third sacral vertebra—often, indeed, at the level of the second.

At its upper end the rectum, following the curve of the sacrum, slopes downwards and at the same time slightly backwards; its middle portion is practically vertical, but the terminal third or more is directed downwards and forwards at an angle varying from 45° to 60° with the horizontal. The pelvic floor, upon which this latter part rests, forms here a similar angle with the horizontal. The bend which the bowel makes behind the lower end of the prostate, where the rectum passes into the anal canal, is, as pointed out above, abrupt, and usually approaches a right angle, so that the anal canal itself slopes downwards and backwards at an angle of nearly 45° with the horizontal.

Not uncommonly the abrupt curve, at the junction of the rectum with the anal canal, presents in front a knuckle-like projection (well seen on mesial section), immediately above the canal. It is most marked in females, and sometimes appears as if the bowel were doubled back upon itself at this point. The floor of the pouch thus formed may dip down in front, even below the level of the upper aperture of the anal canal. This condition is most common in multiparæ, and is evidently due to the relaxed condition of the pelvic structures, and the slight support afforded by the perineal body to this part of the gut in these, and the great capacity and shallowness of the pelvis in the female.

In *length* the rectum usually measures about 5 or 6 inches (12·5 to 15·0 cm.), but it may be much longer.

Its *diameter* is smallest above, near the junction with the pelvic colon, and is greatest below, near the anal canal, where there is a special enlargement known as the **rectal ampulla** (ampulla recti). When empty the rectum measures little over an inch (2·5 cm.) in diameter, but in a state of extreme distension it may be as much as 3 inches (7·5 cm.) in width.

**Peritoneal Relations of the Rectum** (Figs. 773 and 823).—As a rule the upper two-thirds of the rectum has a partial covering of peritoneum—in front and at the sides at first, later on in front only—whilst the lower third has no peritoneal investment whatsoever. When the mesocolon ceases at the end of the pelvic colon, its two layers separate and leave the back of the rectum destitute of peritoneum. Very soon the membrane quits its sides also, and is then found on

the front only; so that the greater part of the rectum lies behind or beneath the pelvic peritoneum, as it were, and is capable of expanding and contracting without being in any way hampered by its partial peritoneal coat.

From the front of the rectum the peritoneum is carried forwards to the base of the bladder in the male, forming the floor of the **recto-vesical** or **recto-genital pouch** (excavatio recto-vesicalis, Fig. 823). In the female it passes to the upper part of the posterior wall of the vagina, forming the floor of the **pouch of Douglas** (excavatio recto-uterina Douglasi, Fig. 818). Whilst at each side, in both sexes, it passes from the front of the rectum on to the posterior wall of the pelvis, forming the bottom of a large fossa, seen at the sides of the rectum when that bowel is empty, and known as the **pararectal fossa.** With distension this fossa is encroached upon by the enlarging bowel, and soon is obliterated.

The level at which the reflection of the peritoneum takes place from the front of the rectum is of considerable practical importance in connexion with operations in this region. As a general rule this reflection, that is, the bottom of the recto-vesical

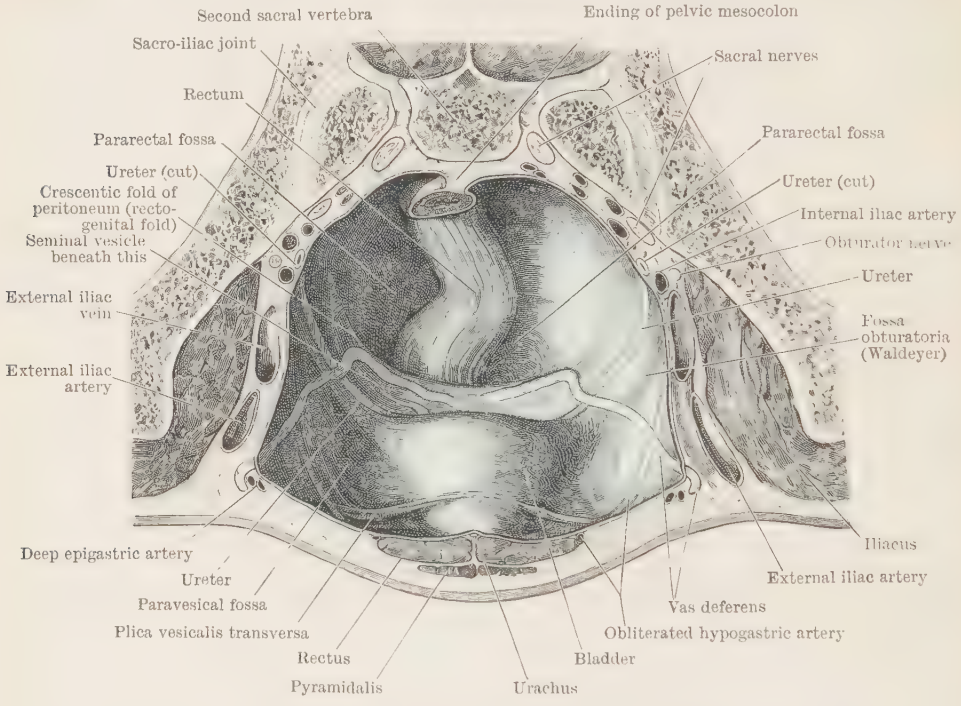

Fig. 773.—The Peritoneum of the Pelvic Cavity.

The pelvis was sawn across obliquely in a thin male subject aged 60. Owing to the absence of fat the various pelvic organs are visible through the peritoneum, though not quite so distinctly as represented here. The bladder and rectum are both empty and contracted; the paravesical and pararectal fossæ, as a result, are very well marked.

pouch, is placed at a distance of 1 inch (2·5 cm.) above the base of the prostate, or about 3 inches above the anus, but the level is subject to considerable variation, being as a rule relatively much higher in well-developed muscular or fatty subjects, whilst it is usually lower in emaciated bodies, owing to the thinness of the structures forming the pelvic floor.

The bottom of the recto-vesical fossa may reach down in an extreme case to within an inch (2·5 cm.) of the anus, whilst it is not at all rare to find it within 2 inches (5·0 cm.) of that orifice; on the other hand, it may be considerably higher than normal, sometimes being placed at a distance of 4 or 4½ inches (10·0 to 11·2 cm.) from the anus. It should also be added that the level is generally believed to be somewhat raised by distension of the rectum and bladder, and lowered by emptying these viscera, although this is denied by Jonnesco.

In the child at birth, the peritoneum extends down to the base of the prostate (Symington), and is thus lower in relation to the bladder; but this may be partly accounted for by the high position of this organ in the child.

As a rule it will be found that 2 inches (5·0 cm.) of the front of the rectum, exclusive of the anal canal, are entirely free from peritoneum, and it is this and the adjacent portion of the bowel which, being free from the restraining influence of the peritoneum, is most distensible, and is known as the **rectal ampulla**. Including the anal canal, 3½ inches (8·7 cm.) of the rectum, *measured along the front of the tube*, have no serous covering. On the other hand, the back is free from peritoneum for 5 or 6 inches (12·5 to 15·0 cm.)—or sometimes much more—above the anus.

It is also of interest to notice that the connexion of the peritoneum to the rectum varies in its character at different parts:—Above and in front it is closely adherent, and can be removed only with the greatest difficulty; at the sides and below the connexion is much looser. As a result, the peritoneum can be stripped off the rectum in its lower third or half without much difficulty, whilst in its upper portion this is not the case—an arrangement which admits of the free expansion of the rectal ampulla.

**General Relations of the Rectum** (Figs. 771 and 772).—*Behind*, the rectum rests on the front of the sacrum and coccyx, and below these upon the posterior part of the pelvic floor—here formed by the meeting of the two levatores ani in the ano-coccygeal raphe. When much distended it also comes into relation on each side with the lower part of the pyriformis and the sacral plexus. The bowel is separated from these structures by a very considerable amount of connective tissue, arranged (apparently in several layers) around the tube. In this tissue the two chief branches of the superior hæmorrhoidal vessels lie behind the upper part of the bowel, but lower down they are placed in relation to its sides.

*At its sides* above are the pararectal fossæ and their contents (pelvic colon, or ileum); below this the rectum is in contact with the coccygei and levatores ani muscles, which run backwards to the coccyx on each side of the bowel. The branches of the superior hæmorrhoidal vessels are also found running down on its muscular coat, as far as the middle of the rectum, where they pierce the wall of the bowel.

*In front*, the rectum is separated from the bladder, to within an inch of the prostate, by the recto-vesical pouch of peritoneum, which usually contains some coils of small intestine. Below the reflection of the peritoneum the front of the bowel is in contact with the base of the bladder, the vasa deferentia, vesiculæ seminales, and the back of the prostate gland (Fig. 772), from all of which it is separated by the recto-vesical layer of the pelvic fascia. *In the female* (Fig. 777) the rectum is separated from the posterior surface of the uterus and the upper end of the vagina by the pouch of Douglas and the intestine which it usually contains. Below the peritoneal reflection it is in direct contact with the posterior vaginal wall, to which it is connected loosely above, but more closely below.

The lower portions of the rectum and bladder in the male are separated by the recto-vesical fascia only, over a narrow triangular area which measures about an inch (2·5 cm.) in vertical height. The base of this triangle corresponds to the reflection of the peritoneum from one organ to the other, and the apex to the base of the prostate, whilst the sides are formed by the vasa deferentia, which lie very close to one another except above, near the base of the triangle, where they diverge rather abruptly (Fig. 772). Through this triangle the operation of tapping the bladder from the rectum is performed.

The vesiculæ seminales, unless when of a small size, slope outwards and backwards round the front and sides of the distended rectum (Fig. 772), which they thus embrace, as it were, within their grasp.

The ureters, as they run inwards towards the base of the bladder, lie close in front of the vasa deferentia, and are not far separated from the distended rectum (see Fig. 772).

The portion of the rectum below the level of the peritoneal reflection is surrounded by the **rectal fascia**, a layer of connective tissue which is derived from the visceral layer of the pelvic fascia.

In the **child** the rectum, or at least its upper part, is relatively larger, and it pursues a much straighter course than in the adult. As pointed out above, its peritoneal covering likewise descends lower at birth, and reaches as far as the base of the prostate.

## THE ANAL CANAL.

**Anal Canal** (pars analis recti—third part of the rectum of the old descriptions).—In order to reach the exterior, it is necessary for the lower end of the

bowel to pierce the floor of the pelvis. This it does by passing through the narrow interval left between the mesial borders of the levatores ani muscles (Fig. 771). As it passes between them, the two muscles pinch in the tube, and by the apposition of its lateral walls obliterate its cavity, reducing it to a mere slit-like passage. This passage, through which the rectum communicates with the exterior, is the "anal canal" (Symington).

Formerly this terminal portion of the tube was described as the "third part of the rectum," and, like the rest of that bowel, it was supposed to form a reservoir for the retention of the fæces. Symington pointed out that this was not the case. He showed that the canal was not of the same nature as the rest of the rectum, but that it was a mere passage through which the bowel discharged its contents, the relation between the two being practically the same as that between the urethra and the bladder in the female. It is probable, however, that, when the rectum is distended, the upper part of the anal canal is often, if not usually, occupied by the wedge-shaped lower end of the contained fæcal mass, whilst the chief bulk of the contents is supported by the rectal valves and the levatores ani.

The anal canal *begins* where the rectum proper terminates, namely, at the level of the levatores ani muscles, opposite the lower part of the prostate. When the distended rectum is cut across near its lower end, in a hardened body, and the cavity examined from the interior, a distinct projection, formed by the inner border of the levator ani (pubo-rectalis, or sphincter recti portion), is seen on each side, indicating the upper limit of the canal. It is said that these ridges can also be felt during life by the finger introduced into the rectum (Cripps). Below, the anal canal *ends* at the anus, or anal orifice, by opening on the exterior.

Its *length* is usually from 1 to 1½ inches (2·5 to 3·7 cm.), being greater when the bowel is empty, and less when it is distended. Its antero-posterior diameter when closed varies between ½ and ¾ inch (12 to 19 mm.).

The *direction* of the anal canal, as already pointed out, is downwards and backwards, often forming an angle of nearly 45° with the horizontal, although it is usually somewhat nearer to the vertical.

**Relations.**—It is *surrounded* by both the external and internal sphincters, and above also by the borders of the levatores ani, these muscles forming a muscular cylinder around it (Fig. 771). *On each side* is situated the ischio-rectal fossa with its contained fat, which allows of the distension of the canal during the passage of fæces. *Behind* is placed a mass of mixed connective and muscular tissue, known as the **ano-coccygeal body** (Symington), which intervenes between it and the coccyx. Finally, *in front*, it lies close behind the bulb of the urethra and the base of the triangular ligament in the male, and a sound in the urethra can be easily felt by the finger introduced into the anal canal, particularly in thin bodies. In the female it is separated from the vagina by the wedge-shaped mass of fatty and muscular tissue known as the "perineal body."

**Structure of the Rectum and Anal Canal.**—The wall of the rectum is made up of four coats, viz.:—1. The **outer coat**, formed in part of peritoneum (already described), and, where the peritoneum is absent, of connective tissue which can be dissected off in several layers. In this connective tissue the hæmorrhoidal vessels run until they pierce the wall of the tube. In it also, at the back and sides of the rectum, are found embedded a number of rectal lymphatic glands.

2. The **muscular coat**, which is much thicker than in any other portion of the intestine, is composed of two stout layers of unstriped muscle—an outer longitudinal and an inner circular—like that of the intestine generally. The *longitudinal fibres*, although present all round, are chiefly accumulated on the front and back of the tube (see p. 1089), where they form two broad bands; at the sides they are reduced to a thin layer, the deepest fibres of which are folded in and take part in the formation of the rectal valves.

Where the rectum pierces the floor of the pelvis, the outer layer of longitudinal fibres is united to the deeper portion of the levator ani, partly by tendinous fibres and partly by an interchange of muscular fibres, between the levatores and the muscular coat of the rectum. This interchange of fibres, however, is denied by Peter Thompson and Browning. Below, the longitudinal fibres pass between the external and internal sphincter muscles, or through the latter to join the skin around the anus. The folding of the rectum from side to side, described above, is brought about and maintained by the shortness of the fibres of this coat on the front and back of the bowel.

In saggital sections of the pelvis near the mesial plane there can generally be seen a distinct band of red, longitudinally-arranged, muscular fibres, which descends on each side from the front

of the coccyx to blend with the longitudinal fibres on the back of the rectum. This band is the **recto-coccygeus muscle.** It is composed of striped fibres above, but becomes unstriped below.

Some unstriped muscular fibres which are found descending in the subcutaneous tissue of the lower part of the anal canal, to join the skin around the anus, have been described by Ellis as the **corrugator cutis ani.** According to Roux, they are some of the longitudinal fibres of the rectum which have passed through the internal sphincter to the submucous tissue, and then descended to the skin.

The *circular fibres* form along the whole length of the tube a continuous layer, which is doubled inwards to assist in the formation of each rectal valve, and is thickened below to form the internal sphincter of the anus. The **internal sphincter** (sphincter ani internus), as just pointed out, is formed by a great, and rather sudden, increase of the circular muscular fibres, which begins at the upper end of the anal canal. It surrounds the canal for about an inch (2·5 to 3·0 cm.), and terminates $\frac{1}{4}$ or $\frac{1}{3}$ inch (6 or 7 mm.) above its lower aperture (Fig. 775).

3. The **submucous coat** is composed of loose areolar tissue, which allows of a free movement of the mucous layer on the muscular coat, and which also admits, under certain abnormal conditions, of a prolapse of the mucous membrane through the anal orifice. The hæmorrhoidal plexus of veins is contained in this layer.

4. The **mucous coat** must be considered separately in the rectum and anal canal. That of the rectum is redder in colour than the mucous membrane of the colon, as a result of its greater vascularity. It is also thicker, and owing to the looseness of the underlying submucosa, is thrown into numerous irregular rugæ when the rectum is empty; these disappear when the bowel is distended, and there then become evident three (sometimes more, sometimes less) crescentic folds, which are much less noticeable in the empty state, and which have been already referred to as the rectal valves. Lymphoid nodules and glands of Lieberkühn are present; but these latter are not so numerous as in the colon, although their calibre is greater.

The *mucous membrane of the anal canal* presents in its upper half a number of vertical ridges known as the *columns of Morgagni*; between the lower ends of these are found a series of small semilunar folds which are disposed horizontally around the passage and are called the *anal valves* (Fig. 775). Above the level of the anal valves the canal is lined by a modified mucous membrane resembling that of the rectum; the portion below the valves (*i.e.* the lower 12 to 16 mm. of the canal) is covered by modified skin, continuous with that around the anus.

The mucous membrane of the rectum presents a characteristic punctated appearance, which is due to the presence of a considerable number of rounded depressions, such as might be made by firmly pressing a finely-pointed pencil against the membrane. These *rectal pits*, of which we can find no previous description, are tubular in form, and have an accumulation of lymphoid tissue at the bottom of each; the whole appearance being such as might be produced if a small solitary gland were drawn down from the surface into the intestinal wall.

Fig. 774.—Diagram of Rectum, showing Houston's valves in interior.

The diagram is a reduced tracing of Fig. 772. After removal of the prostate, etc., an aperture was made in the anterior wall of the rectum, through which two rectal valves can be seen corresponding to lateral inflections on the exterior. The levator ani is also shown, and its relation to the beginning of the anal canal is suggested.

**Rectal Valves,** or **Valves of Houston** (plicæ transversales recti).—These, sometimes termed the valves of Kohlrausch, are crescentic shelf-like folds which project into the cavity of the rectum on its lateral aspects (Fig. 774). They are composed of an infolding of the mucous, submucous, and greater part of the muscular coats, and their form is preserved by the relative shortness of the anterior and posterior bands of longitudinal muscular fibres. They are produced, as pointed out above, by the projection, into the interior of the bowel, of the creases on the exterior which result from the lateral inflections of the rectum. In the majority of cases three are present (there may be four, five, or, it is said, even more), but often the lowest of the three is small or absent; or all the valves may be ill-developed and indistinct. When mesial sections of the *empty* rectum are

examined, the valves are not easily seen, as they then project but slightly, and are almost completely hidden amongst the numerous rugæ of the mucous coat. They are most evident in a distended rectum which has been hardened *in situ*; they can also be seen during life, *per anum*, with the aid of a rectal speculum.

As a rule two valves are found on the left and one on the right side; this latter is generally the largest, and is situated a little above the level of the peritoneal reflection, viz. 3 or $3\frac{1}{2}$ inches (7·5 to 8·7 cm.) above the anus; the other two valves are found about 1 to $1\frac{1}{2}$ inches (2·5 to 3·7 cm.) higher up and lower down respectively. The valves are distinctly marked in the fœtus (see Fig. 775), and seem to constitute an essential part of the human rectum, their use being to support the contents of the rectum, which they break up into segments, each supported by a valve (see p. 1089). They are said to interfere sometimes with the introduction of an enema tube.

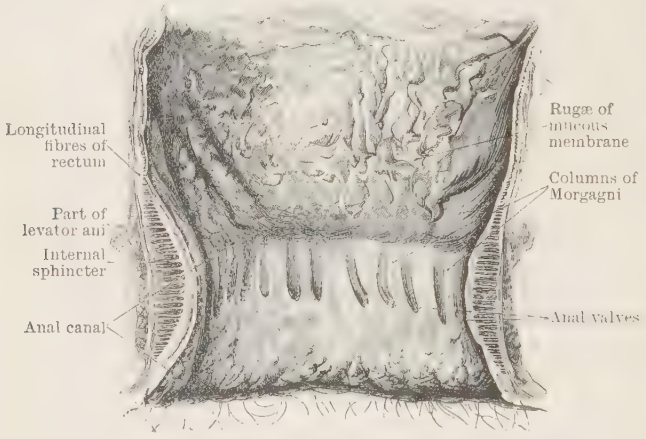

FIG. 775.—THE INTERIOR OF THE ANAL CANAL AND LOWER PART OF RECTUM,

Showing the columns of Morgagni and the anal valves between their lower ends. The columns were more numerous in this specimen than usual.

The rectum in animals generally is free from the lateral inflections described above, and the condition found in man is evidently an adaptation to the erect attitude. In quadrupeds the contents of the rectum do not press unduly on the sphincter, owing to the horizontal position of the body. With the assumption of the erect attitude, on the other hand, the whole weight of the contents would be thrown on the sphincters, were it not for the lateral foldings and the resulting shelves.

**Columns of Morgagni** (columnæ recti Morgagni).—The mucous membrane of the anal canal presents, in its upper, and part of its middle thirds, a number (5 to 10) of *permanent* vertical folds, separated by grooves, and known as the columns of Morgagni (Fig. 775). They are usually $\frac{1}{3}$ to $\frac{1}{2}$ inch (8 to 12 mm.) in length, $\frac{1}{8}$ to $\frac{1}{4}$ inch (3 to 6 mm.) in width, and they extend down to within $\frac{1}{2}$ or $\frac{2}{3}$ inch (12 to 7 mm.) of the anal aperture. They are formed by infoldings of the mucous membrane, containing in their interior some unstriped muscle derived from the muscularis mucosæ, and also, as a rule, an artery and a vein.

Very often the contained vein presents an enlargement, or a knob-like tortuous plexus in the lower part of the column; below this the plexus is continued down beneath the mucous membrane of the lower zone of the anal canal into the anal veins (see p. 1095). This portion has accordingly been described as the hæmorrhoidal zone of the anal canal. Sometimes the columns of Morgagni are very indistinct; occasionally no trace of them can be found, although in the fœtus (Fig. 776) they are usually well marked.

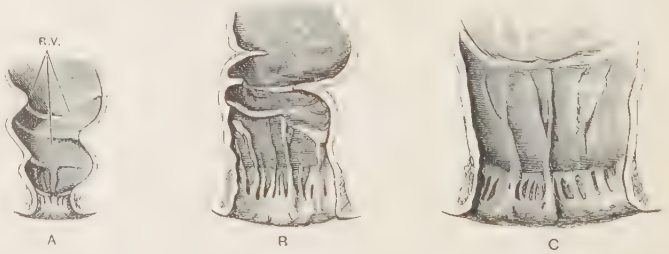

FIG. 776.—THE ANAL CANAL AND LOWER PART OF RECTUM IN THE FŒTUS.

A, aged 4 to 5 months; B, 6 months; and C, 9 months. In each the anal canal is distinctly marked off from the rectum proper; the columns of Morgagni and the rectal valves are distinct. R.V, Rectal valves.

**Anal Valves** (of Morgagni).—If a probe be passed downwards along the groove which separates two adjacent columns of Morgagni (Fig. 755), its point will usually catch in a small crescentic fold which joins the lower ends of the two columns. These little folds, which resemble in miniature the segments of the semilunar valves of the heart, are the anal valves. They project inwards and upwards, and behind each is found a little pocket-like **sinus** (sinus rectalis).

These valves were first described by Morgagni. Recently the view has been advanced by Ball that they are the remains of the embryonic cloacal or anal membrane; and he explains the production of "painful fissure of the anus" by the tearing down of one of them during defæcation by hardened masses of fæces.

The epidermis is continued in a thin and modified form from the exterior up along the anal canal as far as the margins of the anal valves; and the view is pretty generally held that only this lower portion of the anal passage is formed from the proctodæum in the embryo. The junction of the skin with the mucous membrane is indicated by a fine wavy line ("white line" of Hilton—ano-cutaneous line of Hermann) which runs around the bowel at the level of the valves. The mucous membrane of the region immediately above the anal valves is of a more or less transitional nature; glands are absent from it, and over the columns of Morgagni it is said to be covered with stratified epithelium, the superficial cells of which are flattened, whilst in the grooves between the columns the epithelium is columnar. In the upper zone of the anal canal the mucous membrane gradually approaches to the rectal type, but the Lieberkühn's glands and lymphoid nodules are few and scattered.

**Anus or Anal Orifice.**—At the inferior aperture of the anal canal, the modified skin of its lower zone passes into the ordinary skin. A little way outside the orifice, hairs, sebaceous glands, and large modified sweat-glands (glandulæ circumanales) appear.

**Action of the Sphincters.**—In connexion with the anal canal are found three muscles—namely, the paired levatores ani, the external sphincter, and the internal sphincter—the action of which may be briefly referred to here.

**Levator Ani.**—The fibres of the levator which arise from the pubis (pubo-coccygeus or sphincter recti portion) pass backwards on each side of the beginning of the anal canal, and, in great part, meet behind the passage. These two muscular bands—which are but a little distance apart at their origin, and are actually united behind the bowel—are closely approximated during the contraction of the muscles, like the limbs of a clamp, and, pressing on the sides of the anal canal, they assist in closing the upper part of that passage, whilst at the same time drawing it slightly towards the pubes. There is little doubt that the levator ani in this way acts as one of the chief sphincters of the bowel; and it should be noticed that it is placed where its action would be most effective, namely, opposite the point at which the rectum is narrowed or "pinched in" to form the anal canal. In addition to its sphincter action the muscle supports the expanded bowel immediately above the anal canal, and in this way sustains the weight of the fæces when the rectum is distended. It is probably relaxed during defæcation, except perhaps at the completion of the act. The muscle is under the control of the will.

The **external sphincter** forms a muscular cylinder around the lower two-thirds of the anal canal, with (except in the case of some of its inner fibres) an anterior and a posterior attachment. When the muscle contracts, its fibres are tightly stretched between its two attachments, and the space between them is reduced to a narrow antero-posterior slit. By this action the anal canal is flattened from side to side and closed, so that, whilst the levator ani is the sphincter of the upper aperture of the anal canal, the external sphincter closes its lower and greater part. It is under the control of the will, but under ordinary circumstances it is in a state of tonic contraction.

The **internal sphincter** is merely a thickening of the circular muscular coat at the lower end of the bowel. It is continuous with the circular fibres of the gut, not only in structure, but probably also in action, its chief use being to empty the anal canal completely, after the passage of each fæcal mass. Owing to the fact that the canal is an antero-posterior slit, not a circular orifice, and that the internal sphincter forms a muscular ring around it, acting alone, it is scarcely competent to keep the sides of the canal in apposition, and probably it acts rather as a detrusor than a true sphincter of the anal passage.

**Vessels.**—The rectum and anal canal receive their blood supply from three chief sources, namely, the three hæmorrhoidal arteries; to these another less important, though constant, source may be added—the middle sacral artery.

1. The **superior hæmorrhoidal**, the principal artery of the rectum, is the prolongation of the inferior mesenteric trunk (Fig. 634, p. 840). At first it descends in the root of the pelvic mesocolon until the rectum is reached. Here it divides into two chief branches which run downwards and forwards around the sides of the rectum—the right, usually the larger, lying more behind, the left more to the front, and the two, as it were, embracing the bowel between them (Fig. 771). From these two arteries come off secondary branches (about five to eight in all), which pierce the muscular coat about the middle of the rectum, and then descend in the submucosa as a series of longitudinally-running "terminal branches" as far as the anal valves, above the level of which one is usually found beneath each column of Morgagni. These terminal branches give off numerous twigs in their course, which form a hæmorrhoidal plexus in the submucosa by

anastomosing with one another, and also with branches of the middle, and, in the lower part of the bowel, of the inferior hæmorrhoidal artery.

2. The **middle hæmorrhoidal arteries**, two in number—one on each side—are usually branches of the anterior division of the internal iliacs; they run down on the side wall of the lower part of the rectum, and after giving off branches to the bladder, seminal vesicles, prostate (or vagina, according to the sex), each breaks up into four or five small branches, some of which supply the muscular wall of the lower part of the rectum, whilst the others pierce the muscular coat near the upper end of the anal canal, and join in the submucosa with the plexus formed by the superior hæmorrhoidal artery already described.

3. The **inferior hæmorrhoidal arteries**, generally two or three in number on each side, arise at variable levels from the internal pudic arteries, whilst these latter are situated on the outer side of the ischio-rectal fossæ. They pass inwards and downwards through the fat in the fossæ, and, near the wall of the anal canal, break up into branches, some of which are distributed to the levatores ani and the sphincters, whilst others pierce the sphincters and break up in the submucosa into a close network which supplies the lower part of the anal canal, and communicates above with the plexus formed by the superior and middle hæmorrhoidal arteries. The inferior hæmorrhoidal artery is distributed chiefly on the back, and the middle hæmorrhoidal chiefly on the front of the lower part of the bowel.

4. One or more small branches of the **middle sacral artery** reach the back of the rectum, where they are distributed chiefly, if not solely, to the muscular coat.

**Anastomosis of the Hæmorrhoidal Arteries.**—The superior and middle hæmorrhoidal arteries anastomose freely, not only in the hæmorrhoidal plexus of the submucosa, but also, as a rule, by a few large branches on the exterior of the bowel: some perforating branches of the middle sacral also join the plexus in the submucous layer at the lower part of the rectum, as do numerous small branches from the inferior hæmorrhoidal arteries which pierce the sphincters. In addition, small branches of these several arteries unite with one another in the muscular coat. It should be remarked that the superior hæmorrhoidal artery supplies both the muscular and mucous coats above, whilst it is confined to the latter in the lower few inches of the gut, the muscular coats here being supplied by the middle and inferior hæmorrhoidal vessels.

**Veins of the Rectum and Anus.**—These form two chief plexuses of large vessels devoid of valves, namely, the internal hæmorrhoidal plexus situated in the submucous coat, and the external hæmorrhoidal plexus in the outer coat. The **internal hæmorrhoidal plexus** takes origin near the margin of the anus in a number of small (anal) veins, which are radially disposed beneath the skin of the anus, and communicate below with the rootlets of the inferior hæmorrhoidal vein over the external sphincter. These **anal veins**, traced upwards, join together, and are joined by others from the surrounding parts to form larger and often tortuous vessels, which ascend in the columns of Morgagni, where they frequently present ampullary enlargements, varying in size up to that of a small pea, which are said to be the starting-points of hæmorrhoids. Passing upwards, the veins are known as the "terminal veins"; they communicate freely with one another, forming the plexus, and unite into still larger vessels, which pierce the muscular coat about the middle of the rectum, and join the two branches of the superior hæmorrhoidal vein.

From the lower part of the internal hæmorrhoidal plexus numerous vessels pass through the external sphincter to join a venous network on the outer surface of that muscle, from which the **inferior hæmorrhoidal veins** arise. This network, as pointed out above, also communicates with the internal hæmorrhoidal plexus, through the anal veins which descend from the latter beneath the skin of the anal canal, to the exterior of the sphincter.

The various veins which pass out through the walls of the rectum unite freely on its exterior to form a rich venous plexus (**external hæmorrhoidal plexus**), through which the three hæmorrhoidal vessels are brought into free communication with one another. Passing off from this plexus, the **superior hæmorrhoidal vein** joins the inferior mesenteric, which opens into the portal vein; the middle hæmorrhoidal joins the internal iliac, a tributary of the vena cava; and the inferior hæmorrhoidal joins the internal pudic, a tributary of the internal iliac. Thus, on the rectum, a free anastomosis is established between the veins of the portal and systemic circulations.

**Lymphatics.**—Most of the lymphatics of the rectum join a number (four or five) of rectal glands found in the connective tissue coat of the bowel along the superior hæmorrhoidal vein and its two branches, whence they pass to the sacral glands on the front of the sacrum. Some of those from the lower part of the anal canal join the cutaneous lymphatics round the anus, and pass with them to the oblique set of superficial inguinal glands. A few of the lymphatics from the lower portion of the rectum are said (by Quenu) to join the internal iliac glands, but these are inconstant according to Gerota.

**Nerves.**—The nerves of the rectum come partly from the sympathetic and partly from the cerebro-spinal system. The sympathetic fibres are derived on the one hand from the inferior mesenteric plexus, and on the other from the right and left divisions of the hypogastric plexus (*i.e.* the pelvic plexuses), the former accompanying the superior hæmorrhoidal, the latter the middle hæmorrhoidal vessels, to the rectum. The cerebro-spinal fibres arise from the second, third, and fourth sacral nerves soon after these leave the sacral foramina (and constitute the "pelvic splanchnics" of Gaskell). They run forward in the pelvic connective tissue, and joining the pelvic plexuses, reach the side of the rectum. Fibres of the inferior hæmorrhoidal branch of the internal pudic nerve (third and fourth sacral) are also distributed to the lower part of the anal canal as well as to the external sphincter.

It has been shown by experiments on animals, that the cerebro-spinal nerves (from the

second, third, and fourth sacral) convey motor impulses to the longitudinal fibres, but inhibitory impulses to the circular muscular fibres. In like manner the branches from the sympathetic convey motor fibres (derived from some of the lumbar rami communicantes) to the circular muscle, and inhibitory fibres to the longitudinal muscle of the rectum.

The reflex centre which governs the action of the sphincters and the muscular fibres of the rectum ("defæcation centre") is situated in the lumbar region of the cord, and appears to be capable of carrying out the whole act of defæcation even when separated from the brain.

**Variations.**—The best known anomalies found in connexion with the rectum are those classed under the term **imperforate anus** or **atresia ani.** The atresia may be simply due to a partial or complete persistence of the anal membrane (see p. 45), which separates the proctodæum from the hind-gut in the embryo (atresia ani simplex); or the hind-gut may be deficient in its lower part, when there is a considerable interval between the proctodæum and the gut (defectus recti partialis, vel totalis); or the rectum may open into the vagina, the uterus, the bladder, or the ureters, when usually no anus is evident; or finally the cloaca may persist. Other forms are also described, but the foregoing are those most commonly found.

For the **development** of the rectum and anus, see pp 33 and 45.

## THE PERITONEUM.

An introductory sketch of the peritoneum was given on p. 1048; subsequently, when describing the abdominal viscera, an account of its detailed relations to each of these was included. We shall here consider the membrane and its folds as parts of one continuous whole; and we shall also describe its arrangement as seen on horizontal and vertical sections of the abdomen—a favourite method of studying the peritoneum.

As already explained, the peritoneum is the serous membrane which, on the one hand, lines the abdominal cavity, and on the other forms a more or less complete covering for the contained viscera. The portion which lines the walls of the cavity is known as the **parietal peritoneum** (peritoneum parietale), that which clothes the viscera as the **visceral peritoneum** (peritoneum viscerale). The membrane is connected to both walls and viscera by a layer of areolar tissue—the extra or subperitoneal connective tissue—which is considerable in amount in certain regions, whilst it is reduced to a mere trace in others, particularly on the viscera. (The subperitoneal tissue is described at p. 1045).

The peritoneum is described as consisting of **two sacs**—a greater and a lesser. The former lines the greater portion of the abdominal cavity, and invests most of the abdominal viscera; the latter lies chiefly behind the stomach, and is much more restricted in its distribution. It must be clearly understood that these two sacs are not two separate cavities, but simply subdivisions of one great cavity; for the lesser is merely a recess of the greater sac, from which it has become partly shut off by changes that take place in the position of the adjacent viscera during their development. If the great sac be compared to a bag, the lesser sac might be represented as a pocket lying behind, and opening into it by a narrow orifice—the foramen of Winslow—on its posterior wall.

Speaking generally, the great sac lines the walls of the abdominal cavity, and it also covers the various organs which receive a peritoneal investment, except the back of the stomach, the Spigelian and caudate lobes of the liver, the left suprarenal capsule, the upper surface of the pancreas, and also parts of the spleen, left kidney, and transverse colon; all of which, as well as the parietes behind the Spigelian lobe, are clothed by the small sac.

The **great sac of the peritoneum** is placed between the parietes in front and the abdominal viscera behind. It is composed of two layers, an anterior which lines the anterior abdominal wall, and a posterior which covers the viscera; but this posterior layer is carried forwards by the viscera, so that the two layers come in contact, and the cavity of the sac is practically obliterated.

The **anterior layer of the great sac** covers the anterior abdominal wall completely, from the diaphragm above to the pelvis below. Over the greater part of its extent the connexion of the peritoneum to the wall is by a small amount of fatty extra-peritoneal connective tissue; but below, near the pubic region, the fat is more abundant, and the connexion between the two becomes much looser. This is to allow of the peeling off of the peritoneum, which takes place here during

distension of the bladder. As the bladder enlarges it passes up along the anterior abdominal wall, off which it strips the peritoneum, so that, in the fully distended condition, it may be in contact with this wall, without the interposition of peritoneum, for a distance of two inches (5·0 cm., or occasionally more) above the pubes (Fig. 810).

Running up in this fatty tissue are found five cord-like structures, one placed in the middle line, and two at each side. These are (*a*) the **urachus**—the remains of the allantois of the fœtus—which in the adult is a slender fibrous band connected to the umbilicus above, and to the apex of the bladder below, where it usually becomes much stouter. External to the urachus, and some distance from it (Fig. 773), will be found, in the same fatty tissue, (*b*) two stouter fibrous cords, the **obliterated hypogastric arteries** (arteriæ umbilicales). Traced upwards, these also become more slender, and approach the urachus, along with which they are connected to the umbilicus. Below, they grow thicker, and can be followed backwards along the side wall of the pelvis to the internal iliac arteries, which they join. (*c*) Further out still, the **deep epigastric arteries** are seen running upwards and inwards from the external iliac trunk on each side.

When the anterior abdominal wall is examined from behind, it will be seen that these five structures which lie on the front of the peritoneum carry that membrane inwards towards the abdominal cavity in the form of five more or less distinct ridges, in relation to which are found on each side three peritonal fossæ, known as the **inguinal pouches** or **fossæ** (fovea inguinales).

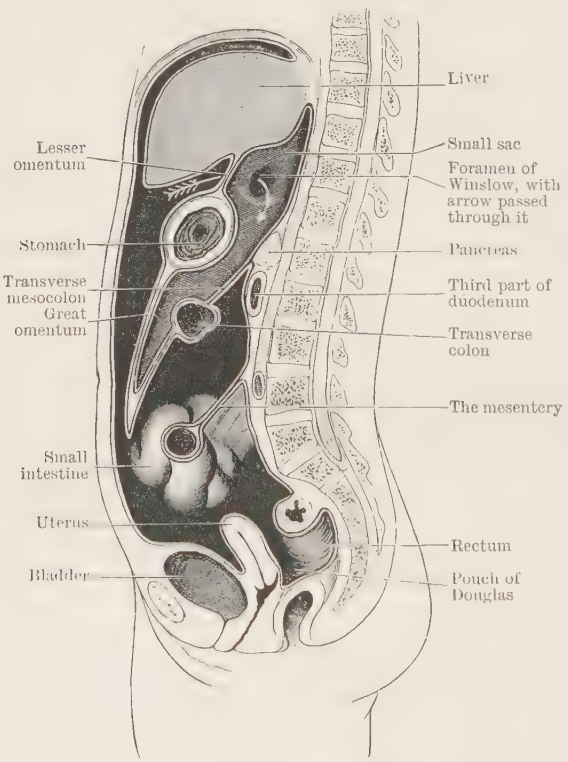

FIG. 777.—DIAGRAMMATIC MESIAL SECTION OF FEMALE BODY, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the small sac is very darkly shaded; the peritoneum in section is shown as a white line: and a white arrow is passed through the foramen of Winslow from the great, into the small sac.

The **external inguinal fossa** (fovea inguinalis lateralis) lies outside the deep epigastric artery, and corresponds to the position of the internal abdominal ring. At its bottom is often found a dimple-like depression of the peritoneum, indicating the point from which the processus vaginalis passed down, in connexion with the descent of the testicle. The **middle inguinal fossa** (fovea inguinalis mesialis) is situated between the deep epigastric and the obliterated hypogastric arteries; whilst the **internal inguinal fossa** (fovea inguinalis interna, fovea supravesicalis) lies to the inner side of the obliterated hypogastric artery, namely, between it externally and the urachus internally. Seeing that the obliterated hypogastric artery, in passing upwards, crosses Hasselbach's triangle, dividing it into an outer and an inner part, it follows that the middle inguinal fossa corresponds to the outer division of the triangle, and the inner fossa to its inner division.

Still another fossa of the peritoneum is seen in this region, just beneath the inner part of Poupart's ligament, corresponding to the position of the femoral or crural ring, and consequently known as the **femoral** or **crural fossa** (fovea femoralis). It may be added that the vas deferens crosses the outer part of this latter fossa, and the obliterated hypogastric artery its inner part. The significance of those fossæ is referred to in connexion with the applied anatomy of the inguinal and femoral regions.

Near the middle line, above the umbilicus, the peritoneum is carried back from the anterior abdominal wall and diaphragm to the parietal surface of the liver in the form of a crescentic fold, the **falciform ligament** of the liver (ligamentum falci-

forme hepatis, described with the liver), which connects the liver to the abdominal wall. This fold lies somewhat to the right of the middle line, and extends almost as low down as the umbilicus. It consists of two layers of peritoneum, between which, in the lower border of the fold, runs the round ligament of the liver—the remains of the umbilical vein of the fœtus.

**Posterior Layer of the Great Sac.**—After clothing the anterior abdominal wall, in the manner just described, the anterior layer of the great sac is continued back on the under surface of the diaphragm, until this latter begins to descend behind the liver, when it is reflected from the diaphragm on to the upper aspect of the liver, and here the anterior passes into the posterior layer of the great sac. The posterior layer first clothes the upper aspect of the liver, then turns round its anterior border, and is continued back on the under surface as far as the attachment of the lesser omentum, where it quits the liver and passes down, as the anterior layer of the lesser omentum, to the lesser curvature of the stomach.

The line of reflection from diaphragm to liver is interrupted near the mesial plane by the falciform ligament. The portion lying to the right of this fold forms the upper layer of the coronary ligament; that to the left of it, the upper layer of the left lateral ligament of the liver.

The extent to which the peritoneum of the great sac passes back on the under surface of the liver varies according as it is traced at the right, the left, or the middle portion of the liver. It clothes the right portion as far back as the lower edge of the uncovered area of the liver, where it is reflected on to the posterior wall of the abdomen and the top of the right kidney (constituting the hepato-renal ligament), as the lower layer of the coronary ligament. On the left portion it is continued back as far as the posterior border of the left lobe—or even a little way on to its upper surface—whence it passes to the diaphragm as the inferior layer of the left lateral ligament. The middle region of the under surface it clothes only as far as the portal fissure and the fissure of the ductus venosus; from these the peritoneum is carried down as the anterior layer of the lesser omentum to the lesser curvature of the stomach, where we shall return to it directly.

The peritoneum, which passes back on the under surface of the diaphragm to the left of the liver, is continued down on the posterior abdominal wall, behind the fundus of the stomach and the spleen, until the left kidney is reached. It covers the upper and outer part of the kidney, and is then carried forward as the **lieno-renal ligament** to the spleen, around which it passes—clothing its renal, phrenic, and gastric surfaces—as far as the hilum (Fig. 779); from this it is carried to the stomach as the anterior layer of the **gastro-splenic omentum**. Similarly, the under layer of the left lateral ligament is continued down on the back part of the diaphragm to the œsophagus, the anterior and left sides of which it clothes. It also forms a little fold at the left of the œsophagus, known as the **gastro-phrenic ligament** (see p. 1057 and Fig. 780).

At the right side, the portion of the peritoneum which forms the under layer of the coronary ligament is carried down over the right kidney (and lower part of the suprarenal capsule) to the duodenum and hepatic flexure, over both of which it passes.

We shall now follow down the posterior layer of the great sac—which we have already traced to the stomach—as seen in a sagittal section (Fig. 770).

Having reached the lesser curvature of the stomach, it passes down over the front of that organ, clothing it completely as far as the great curvature. From this it descends, in front of the transverse colon and small intestine, forming the anterior layer of the great omentum—a large apron-like fold, containing the lower part of the small sac in its interior, which hangs down from the stomach. Arrived at the lower border of the great omentum, the membrane returns on itself, and passes upwards towards the posterior abdominal wall, forming the posterior layer of that omentum. On the way it meets and passes behind the transverse colon, clothing its posterior aspect at the same time (Fig. 777), and is then continued, as the posterior layer of the transverse mesocolon, up to the posterior abdominal wall, which it reaches at the anterior border of the pancreas (Fig. 777).

From the anterior border of the pancreas it is continued downwards again, clothing first the lower part of that organ, then the front of the third portion of the duodenum, and below this the posterior abdominal wall. From this latter, however, it is soon carried forwards again by the branches of the superior mesenteric vessels, passing to the small intestine. Running out along these, it forms the upper (or more correctly, the right) layer of the obliquely-placed mesentery (Fig. 777): on reaching the small bowel at the border of the mesentery, it invests that tube, giving it its serous coat, and then returns—as the under, or left, layer of the mesentery—to the posterior abdominal wall, on which it runs down, covering the great vessels near the middle line, and the psoas muscles and ureters at each side, to enter the pelvis. The mesentery is described at p. 1071.

**Pelvic Peritoneum.**—The detailed arrangement of the peritoneum in the pelvic cavity is somewhat complicated, and is fully described in connexion with the several pelvic organs. A general account will suffice here.

Having passed over the brim all round, it enters the pelvis, and covers its walls as low as the pelvic floor, across which it passes to the various organs. Behind, it invests completely, and forms a mesentery (pelvic mesocolon) for, the pelvic colon, as far down as the third sacral vertebra. Here the colon joins the rectum proper, and the complete investment of the bowel ceases.

As the end of the pelvic colon is approached the two layers of its mesocolon become shorter, and when the rectum is reached, they separate, leaving its posterior surface uncovered, whilst the bowel is clothed in front and at the sides. Lower down, the membrane leaves the sides, and finally, at a point which is usually about 3 inches (7·5 cm., see p. 1089) above the anus, it leaves the front of the bowel,

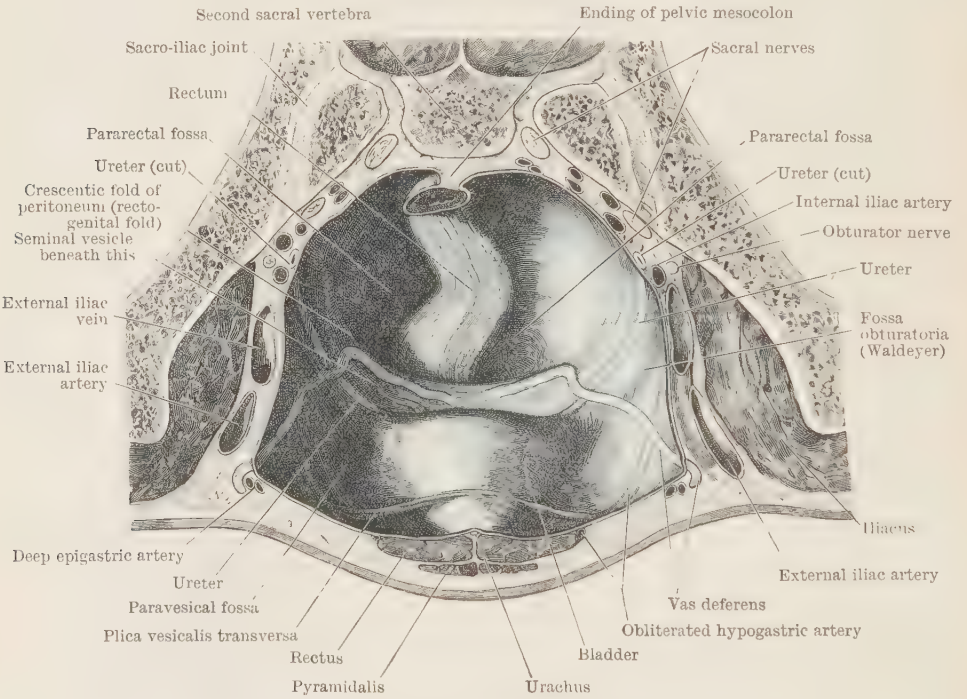

FIG. 778.—THE PERITONEUM OF THE PELVIC CAVITY.

The pelvis was sawn across obliquely (as in Fig. 772) in a thin male subject aged 60. Owing to the absence of fat the various pelvic organs are visible through the peritoneum, though not quite so distinctly as represented here. The bladder and rectum were both empty and contracted; the paravesical and pararectal fossæ, as a result, are very well marked.

and in the male is carried on to the back part of the bladder (here covered by the seminal vesicles and vasa deferentia), forming the floor of the **recto-vesical pouch** (excavatio recto-vesicalis, recto-genital pouch) found between these organs. It then covers the upper surface of the bladder, and passing off from its sides to the walls of the pelvis, constitutes the so-called **false ligaments** of that organ. From the apex of the bladder it is carried on to the anterior abdominal wall by the urachus, thus forming the **superior** or **anterior false ligament** of the bladder (plica pubo-vesicalis).

*In the female* (Fig. 777), the peritoneum, on leaving the rectum, passes to the posterior wall of the vagina, the upper portion of which it covers. From this it is continued up over the posterior surface and fundus of the uterus, and down on its anterior surface as far as the junction of the cervix and body (Fig. 853). Here it passes from the uterus to the bladder, which it partly covers, as in the male, and is then carried on to the anterior abdominal wall. Between the rectum behind, and the uterus and vagina in front, is situated the **pouch of Douglas** (excavatio

recto-uterina Douglasi, recto-genital pouch), the entrance of which is limited on each side by a fold passing from the cervix of the uterus around the sides of the pouch towards the rectum; these are the **folds of Douglas** (plicæ recto-uterinæ Douglasi, recto-genital folds), and they contain in their interior the **utero-sacral ligaments** (musculi recto-uterini), two bands of fibrous tissue with plain muscle fibres intermixed, which pass from the cervix of the uterus, backwards on each side of the rectum, to blend with the connective tissue on the front of the lower part of the sacrum.

Similarly, in front of the uterus, between it and the bladder, is found the much smaller **utero-vesical pouch** (excavatio vesico-uterina). Finally, the peritoneum is prolonged as a wide fold from each margin of the uterus to the side wall of the pelvis, constituting the **broad ligament** of the uterus (ligamentum latum uteri), within which are contained the Fallopian tube, the ovary, the round ligament, and other structures (see p. 1189).

When the bladder is empty, there is seen at each side, between it and the pelvic wall, a considerable peritoneal depression—the **paravesical fossa** (Fig. 778). This fossa is traversed by a peritoneal fold—the plica vesicalis transversa—which is found running transversely outwards from the upper surface of the empty bladder, and, when well marked, passing to the neighbourhood of the internal abdominal ring.

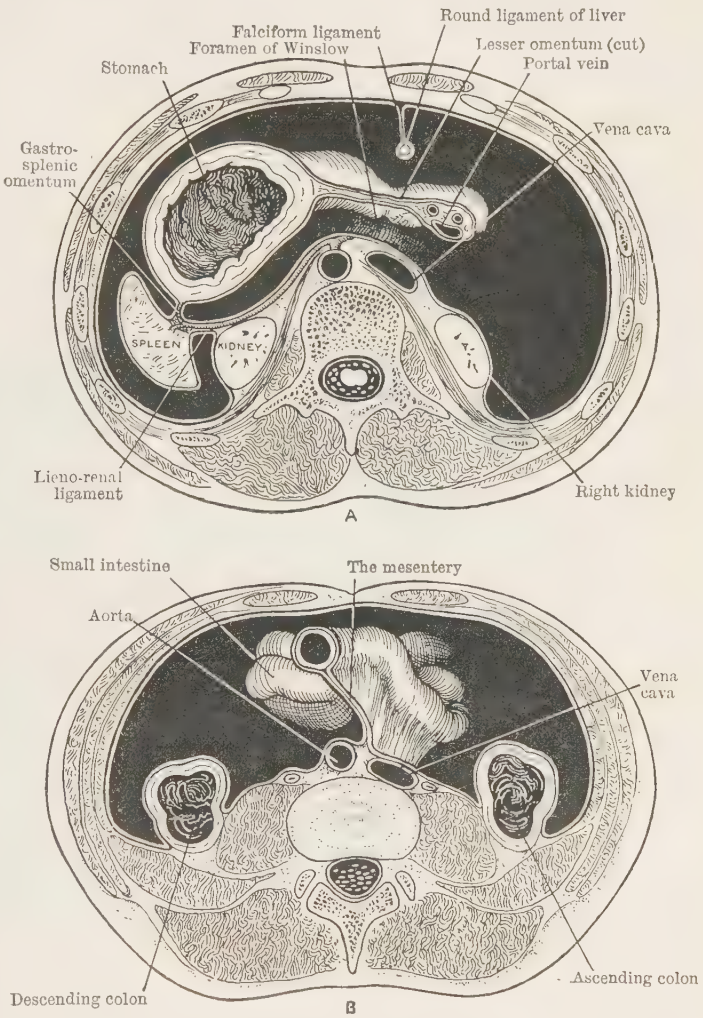

Fig. 779.—Diagrammatic Transverse Sections of Abdomen, to show the peritoneum on transverse tracing. A, at level of foramen of Winslow, B, lower down. In A, note one of the vasa brevia arteries passing to the stomach between the layers of the gastro-splenic omentum, and also the foramen of Winslow leading into the lesser sac which lies behind the stomach.

Above the bladder, on each side of the urachus, is found the **internal inguinal fossa** already referred to (p. 1098). Both of these fossæ are practically obliterated by distension of the bladder.

Similarly, there is seen at each side of the empty rectum, on the posterior pelvic wall, a large depression, which may be known as the **pararectal fossa** (fossa pararectalis, Fig. 778). When the rectum is empty and contracted, these fossæ are filled by intestine; during distension, the rectum increasing in width, expels the intestine and practically obliterates the fossæ.

**Transverse Tracing of the Peritoneum.**—If the peritoneum be followed transversely around the abdomen, just above the level of the iliac crest, where the complications produced by the small sac are absent (Fig. 779, B), few difficulties will be encountered. From the anterior abdominal wall it passes round on each side to the back, lining the lateral and posterior walls. Passing inwards on the posterior

wall, it meets the colon—ascending on the right side, descending on the left—over which it is carried, in each case covering the bowel in front and at the sides only, and leaving the posterior surface bare, as a rule. Sometimes, however, the covering is complete, and a short mesentery is formed. It is next continued inwards over the psoas muscles, the ureters, and the great vessels, on the front of which it meets the superior mesenteric artery and vein running downwards to the intestines. From both sides it passes forwards on these vessels, forming the right and left layers of the mesentery; and finally, having reached the intestine, it clothes it completely, and the two portions become continuous on the bowel.

A transverse tracing at a higher level would include the small sac; it will, therefore, be well to study this portion of the peritoneum before describing such a tracing.

**Small Sac of the Peritoneum** (bursa omentalis).—This, as already pointed out, is a diverticulum of the great sac which lies behind the stomach and adjacent organs, and which communicates with the great sac by a constricted passage, the foramen of Winslow. If the great sac be compared, as already suggested, to a bag, the anterior layer of which clothes the anterior and lateral walls of the abdomen, and the posterior layer the viscera lying on the posterior wall, the small sac would correspond to a pocket lying behind the upper part of the great sac, and opening into its cavity by a narrow mouth, on the right side, just below the liver. From this opening the pocket passes to the left behind the lesser omentum, as far as the spleen, up behind the Spigelian lobe of the liver, and down behind the stomach, and into the great omentum.

As in the case of the great sac, it will of course be understood that the two walls of the small sac and the boundaries of the foramen of Winslow are normally in contact. We shall first consider this opening, and then trace the layers of the small sac.

**Foramen of Winslow** (Fig. 779, A).—This, the constricted passage which leads from the great into the small sac of the peritoneum, is found just below and behind the portal fissure of the liver by running the finger along the under surface of the gall-bladder towards its neck, when, with little difficulty, it passes behind the right margin of the lesser omentum and into the foramen. It is *bounded in front* by the free right border of the lesser omentum, passing up from the first part of the duodenum to the portal fissure, and containing between its two layers the portal vein, hepatic artery, and bile duct. *Behind*, lies the inferior vena cava, covered, of course, by peritoneum. *Above*, is placed the caudate lobe of the liver. And *below*, lie the first part of the duodenum, and the hepatic artery, the latter running forwards and to the right beneath the foramen, before turning up into the lesser omentum. It should be remembered that, normally, the various boundaries of the foramen lie in contact, and that its cavity can only be said to exist as such when its walls are drawn apart.

If we follow the small sac, in through the foramen, it will be found that it expands immediately beyond this narrow opening (Fig. 777), its upper portion lying behind the lesser omentum, and running up behind the Spigelian lobe of the liver as far as its upper end; and its lower portion passing down behind the stomach and on into the great omentum, where it lies in front of the transverse colon, and extends practically to the lower margin of the omentum—although this latter point cannot as a rule be demonstrated in the adult.

As the small sac is composed, like the great, of two distinct layers, an anterior and a posterior, it will be necessary to follow each of these separately. Above, the **anterior layer of the small sac** clothes the Spigelian lobe; it then passes down (from the posterior margin of the portal fissure, and the fissure of the ductus venosus) to the lesser curvature of the stomach as the posterior layer of the lesser omentum. Continued on from this, it clothes the inferior (or visceral) surface of the stomach as far as the great curvature, with the exception of the small "uncovered area" below and to the left of the cardia (Fig. 743, B), but it does not actually come in contact with the œsophagus itself, the back and right side of which are uncovered. On the left, it is reflected from the back of the stomach to the spleen as the deeper layer of the gastro-splenic omentum.

From the great curvature of the stomach it is continued down, forming the posterior layer (of the anterior fold) of the great omentum; and at the lower part

of the omentum it meets and becomes continuous with the posterior layer of the small sac.

The **posterior layer of the small sac**, in passing through the foramen of Winslow, clothes the front of the vena cava (Fig. 779, A); beyond this, it covers the cœliac axis, and passes up to line the slight depression on the posterior abdominal wall (diaphragm), against which the Spigelian lobe rests. Then, passing over to the left, it covers the upper surface of the pancreas, the top of the left kidney and suprarenal capsule, and the inner part of the gastric surface of the spleen (Fig. 780). From the anterior border of the pancreas it is prolonged forwards and downwards—as the anterior or upper layer of the transverse mesocolon—to the transverse colon (Fig. 777).

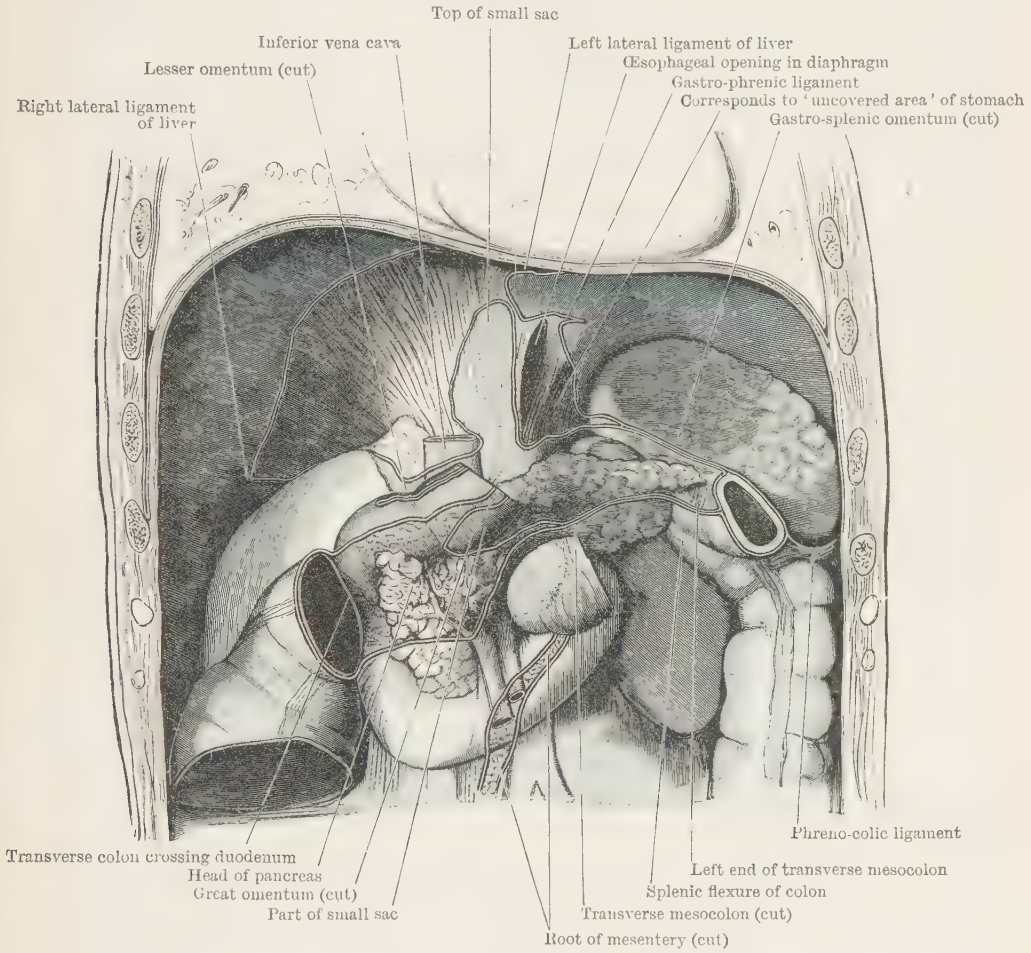

FIG. 780.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

It next clothes the upper aspect of this gut, and is then continued down as the anterior layer of the posterior fold of the great omentum, almost to its lower border, where it becomes continuous with the anterior layer of the small sac, already described.

The transverse tracing at the level of the foramen of Winslow is shown in Fig. 778, A, and can be easily followed without any further description than is there given.

The following additional details may be mentioned:—The small sac is divided by a constriction into two parts—an upper, lying behind the lesser omentum and Spigelian lobe, and a lower, placed behind the stomach and within the great omentum. The constriction is due to the passage of the coronary and hepatic arteries forward around the sac; the former winds round its left side, the latter round its right; and each raises up a fold of peritoneum, which projects strongly into the sac, and partially divides it into two. This can be shown by cutting the lesser omentum along the lesser curvature of the stomach and looking into the cavity.

Where the small sac runs up behind the Spigelian lobe, it forms, as pointed out at page 1116, the left boundary of the uncovered area of the right lobe, and, consequently, a third or left layer of the coronary ligament.

A special diverticulum of the small sac runs out to the right, behind the beginning of the duodenum, to clothe the back of that tube for about an inch (Fig. 780).

The splenic artery reaches the spleen by passing to the left, behind the posterior layer of the small sac, which also extends to that organ (Fig. 779, A).

The **lesser omentum** is described at page 1116; it need only be pointed out now that it is composed of two layers, the anterior derived from the great sac, and the posterior from the small sac, both of which are extremely thin—sometimes even cribriform.

The **great omentum** is a large apron-like fold of peritoneum, usually more or less loaded with fat, which is suspended from the great curvature of the stomach, and hangs down in front of the intestines to a variable extent. When the abdomen is carefully opened without disturbing the viscera, it is rare to find the great omentum evenly spread over the front of the intestines. More commonly it is folded in between some of the coils of intestine, or tucked into the left hypochondrium; or perhaps it is carried upwards in front of the stomach by a distended transverse colon. It extends between the great curvature of the stomach above and the transverse colon below, not taking the shortest course from one of these to the other, but hanging down as a loose fold between the two. The lower part of the small sac is continued down within it (Fig. 777).

The great omentum may be said to consist of two folds, each formed of two layers, one derived from each sac of the peritoneum. The **anterior** or **descending fold** begins at the great curvature of the stomach, where it is formed by the meeting of the two layers from the superior and inferior surfaces of that organ respectively; from this it descends to the lower border of the omentum, where, turning back upon itself (Fig. 777), it passes up as the **posterior** or **ascending fold**. This runs upwards until it meets the transverse colon; here its two layers separate to enclose and cover that colon—and the omentum properly so called ceases. Its two layers, however, unite at the upper surface of the colon (Fig. 777) to form the **transverse mesocolon**, which is continued upwards and backwards to the anterior border of the pancreas. Here the layers of the transverse mesocolon again separate—the upper, derived from the small sac, running backwards and upwards over the upper surface of the pancreas to the posterior abdominal wall; the lower, derived from the great sac, passing downwards along the back of the abdomen, as already explained.

The great omentum is continued to the right for a short distance (25 mm.) along the lower border of the duodenum. At the left end it shortens very much, and is directly continued into the gastro-splenic omentum; the spleen, as it were, being introduced between the two layers instead of the colon.

**Functions of the Great Omentum.**—Numerous uses have been assigned to the great omentum; the chief seem to be: (1) To act as a movable and easily adjustable packing material, capable of filling all temporarily-produced spaces in the abdomen. In this respect it may be compared with the Haversian fatty pads in joints. (2) It probably, to some extent, prevents the passage of the small intestine up into the stomach chamber, and helps to keep them from getting entangled there. (3) It is a storehouse of fat. (4) It is said to be "the great protector against peritoneal infectious invasions." Being freely movable, it can pass to almost any part of the abdomen, and there "build up barriers of exudations to check infection" (Byron Robinson).

Mr. Lockwood has made the interesting observation (in connexion with the contents of herniæ) that, in bodies under forty-five years of age, the omentum can rarely be drawn down below the level of the pubic spine; in older bodies the reverse is the rule.

The **gastro-splenic omentum** is a short fold composed of two layers, the anterior or more superficial being derived from the great sac, the posterior or deeper from the small sac (Fig. 779, A). It is attached by one margin to the wide end of the stomach (just below the line of the great curvature), and by the other to the gastric surface of the spleen just in front of the hilum. Between its two layers the vasa brevia of the splenic artery pass from the spleen to the stomach. Below and in front, its layers are continued into the corresponding layers of the great omentum; above and behind, they separate at the "uncovered area" of the stomach (Fig. 780).

Minor Folds of Peritoneum.—The **phreno-colic ligament**, passing from the splenic flexure of the colon to the diaphragm opposite the 10th or 11th ribs, has

been described in connexion with the splenic flexure. The **mesentery of the appendix**, and the folds and fossæ around the ileo-cæcal region, are included in the account of the cæcum, as are those around the duodenum in the description of that viscus. The **lieno-renal** and **hepato-renal** ligaments have been referred to incidentally above.

## Development of the Intestinal Canal and Peritoneum.

As already explained on p. 32, when the embryo begins to take definite shape, and to be marked off from the general surface of the blastodermic vesicle by an infolding of its margins—resulting in the formation of the cephalic or head fold, the caudal or tail fold, and the lateral folds—a portion of the cavity of the vesicle is cut off by these folds, and more or less completely enclosed within the body of the embryo, to form the **primitive alimentary canal**. This is simply an imperfect tubular cavity, situated beneath the notochord, and bounded towards one end by the head fold, at the other by the tail fold, and at the sides by the lateral folds. The anterior portion of this cavity, situated within the head fold, is known as the **foregut**, and from it are developed the back part of the mouth, the tongue, pharynx, œsophagus, stomach, and the greater portion of the duodenum, together with the organs formed as outgrowths from these. Similarly, the posterior tubular portion, contained within the tail fold, constitutes the **hindgut**, and from it are formed the rectum, except its anal end, and a portion of the colon. The middle division, known as the **midgut**, gives rise to the rest of the digestive tube, and is at first widely open below, where it is continuous with the cavity of the yolk sac. Soon, however, it is gradually closed in by the approximation of the four folds which meet around the margins of the umbilical orifice, and the communication between the alimentary canal and the yolk sac is thus reduced to a narrow passage—the **vitelline** or **vitello-intestinal duct**. This duct joins that portion of the primitive tube which subsequently forms the lower part of the ileum, and a remnant of it is sometimes found in the adult, when it is known as **Meckel's diverticulum** (see p. 1073).

At this stage the primitive canal has the form of a nearly straight tube, blind at both extremities, and communicating only with the cavity of the yolk sac. It is lined throughout by the endoderm, the cells of which form the epithelial lining of the adult canal; outside this it is invested by the splanchnopleure, or splanchnic layer of the mesoderm, and is separated from the somatopleure or body wall by the **cœlom** or **body cavity**, which later on gives rise to the pleural, pericardial, and peritoneal cavities of the body. At the back, the splanchnic mesoderm which surrounds the canal passes dorsalwards, to become continuous with the general mesoderm beneath the notochord, thereby forming a fold which connects the primitive alimentary tube to the dorsal wall of the embryo, and constitutes the **primitive mesentery**. This is at first of considerable thickness. At a later period it becomes reduced to a thin sheet of mesodermic tissue, covered on each side by a layer of flattened endothelial cells, which suspends the primitive alimentary canal within the body cavity of the embryo.

At each end of the embryo, an ingrowth of the ectoderm takes place, which meets and finally becomes continuous with the corresponding extremity of the primitive alimentary tube, giving rise to the mouth and anus respectively. The former of these ingrowths is known as the **stomatodæum**, and from it is formed the epithelial lining of the vestibule of the mouth, of the salivary glands, the gums, and the greater part of the nasal cavity, as well as the anterior lobe of the pituitary body. From the other ingrowth—the **proctodæum**—are formed the anal aperture and probably the anal canal, below the level of the anal valves. An account of the formation of the mouth and the anus will be found on pages 34, 38, and 45.

At an early date special outgrowths of the lining endoderm take place from the portion of the foregut corresponding to the future duodenum. From these diverticula the liver and pancreas are formed: the former grows forwards from the gut, whilst the latter grows backwards into the dorsal mesentery (see pages 1122 and 1129 respectively).

The primitive alimentary canal is now a tubular cavity, suspended from the dorsal wall of the embryo, within the cœlom, by a simple mesentery (Fig. 781). In front, it communicates with the exterior through the stomatodæum or primitive mouth, and in the region of the future duodenum the liver appears as a bifid outgrowth, followed soon by outgrowths for the formation of the pancreas. Finally, at a date which has not been precisely determined, the anal membrane disappears, and its posterior end communicates with the exterior through the proctodæum.

**Stomach.**—As early as the fourth week the foregut exhibits a fusiform enlargement

in the region of the developing heart, which is the first evidence of the differentiation of the stomach: this enlargement is at first symmetrical, and mesially placed. Soon, however, as the diaphragm is being formed, the stomach descends into the abdomen, and its dorsal wall—the future great curvature—begins to grow more rapidly than the ventral wall. As a result the whole organ becomes somewhat curved, and its lower end is carried forwards from the posterior abdominal wall, giving rise to the curvature of the duodenum. The excessive growth of its posterior wall causes the stomach to turn over on to its right side, which now becomes posterior or dorsal. In this rotation its upper or cardiac portion moves to the left of the middle line, and the whole organ assumes an oblique direction across the abdomen. Already, at the fifth or sixth week, the adult form of the stomach is clearly indicated.

This rotation of the stomach around its long axis, which is accompanied by a rotation of the lower end of the œsophagus, explains the unsymmetrical position of the two pneumogastric nerves. In the adult the left nerve is found on the front of the stomach, which was originally the left side of the organ; similarly, the right nerve lies on the back, which was originally the right side.

**Intestines.**—At first there is no separation into large and small intestines; the primitive canal simply forms a slender tube, with a convexity towards the umbilical orifice, through which the vitelline duct passes to the yolk sac. Later, the tube increases in length, and in embryos of 11 or 12 mm. an outgrowth of the canal appears, which represents the future cæcum, and indicates the separation into large and small intestines. Growing longer, the intestine forms a large loop with the vitelline duct springing from its apex (Fig. 781), and the superior mesenteric artery running down between the layers of its mesentery. At the same time the two extremities of the coil approach one another, and form a narrow neck to the loop, as shown in Fig. 781. There now takes place a change which entirely modifies the position of the parts—this is a rotation of the whole loop, with its mesentery, around the superior mesenteric artery as an axis (Fig. 782). The result of this rotation is that the original right side of the loop of gut and mesentery becomes the left side; and the beginning of the large intestine is carried across the duodenum (Fig. 782), thus explaining the passage of the duodenum behind the transverse colon in the adult. At the same time the cæcum comes to lie near the middle of the abdomen below the liver, a position in which it will be found during the third month. Subsequently, it passes farther to the right; and finally, descending, comes to occupy its adult position.

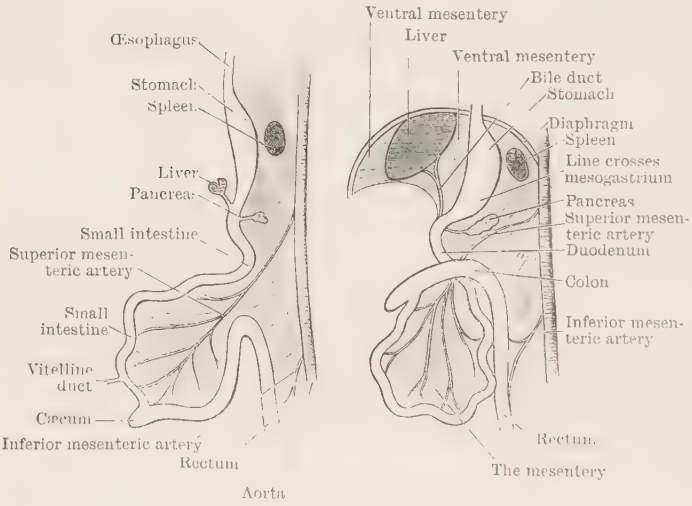

Fig. 781.—Two Diagrams to illustrate the Development of the Intestinal Canal.

The figure to the right shows the rotation of the intestinal loop round the superior mesenteric artery. In both figures the parts are supposed to be viewed from the left side.

The small intestine continues to grow in length, and, as a result, is thrown into coils, which become more and more complex as the length increases, until the adult condition is attained. The terminal portion of the large bowel retains its position on the left side, and passes down to the anus. The development of the cæcum and appendix is described at page 1078.

**Peritoneum.**—At first the primitive alimentary canal is suspended from the dorsal wall of the embryo, along the middle line, by a **simple dorsal mesentery**, which extends along the whole length of the tube, and is common to all its divisions—a condition found in the adult stage of many reptiles. There is also present, in the upper part of the cavity, after the stomach and liver descend into the abdomen, a **ventral mesentery** (Fig.

781), which connects the stomach and duodenum to the back of the liver, and, passing on, connects the front of the liver to the anterior abdominal wall. The portion of this ventral mesentery, between the stomach and liver, becomes the lesser omentum; its anterior portion, between the liver and the abdominal wall, forms the falciform ligament (Fig. 781); and, in its lower margin, the umbilical vein runs from the umbilicus to the liver.

The portion of the dorsal mesentery lying behind the stomach is known as the **mesogastrium**. At first it is relatively short; but with the growth of the posterior wall of the stomach, and the turning of that organ over on its right side, the mesogastrium becomes elongated, and is folded on itself, forming more or less of a pouch, directed downwards and to the left. The wall of this pouch becomes in part the great omentum, and within it is developed the small sac of the peritoneum. In the rotation of the stomach and the accompanying passage of the lesser omentum from an antero-posterior to a more or less transverse direction, a portion of the cavity of the abdomen is, as it were, caught in behind the stomach and lesser omentum. This portion of the cavity becomes the upper part (vestibule) of the small sac, and at first it communicates with the general cavity by a wide opening to the right of the lesser omentum; but the growth of the liver, encroaching upon the opening, and other causes, reduce it to a relatively small size, and it forms the **foramen of Winslow** in the adult.

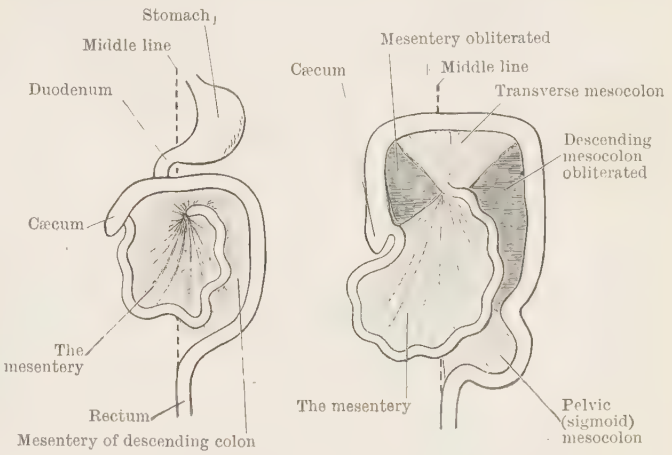

FIG. 782.—TWO DIAGRAMS TO ILLUSTRATE THE DEVELOPMENT OF THE MESENTERIES.

In the first figure the rotation of the intestinal loop and the continuous primitive mesentery is shown. In the second figure (to the right), which shows a more advanced stage, the portions of the primitive mesentery (going to the ascending and descending colons) which disappear, through their adhesion to the posterior abdominal wall, are shaded dark; the portions which persist are lightly shaded.

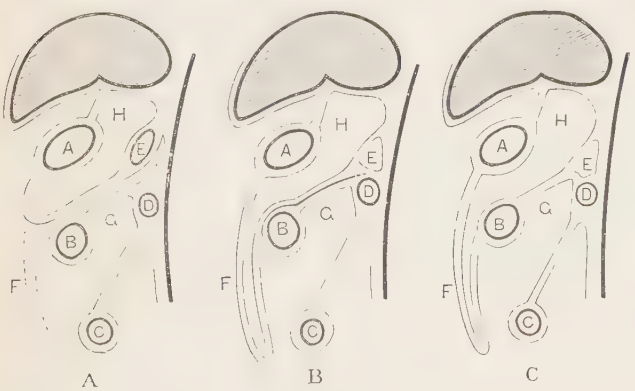

FIG. 783.—DIAGRAMS TO ILLUSTRATE THE DEVELOPMENT OF THE GREAT OMENTUM (after Hertwig).

A, shows the beginning of the great omentum and its independence of the transverse mesocolon; in B, the two come in contact; and in C, they have fused along the line of contact. (According to Lockwood, the two layers of the fold shown in A, running in between the great omentum and transverse mesocolon, instead of fusing, as shown in B, are drawn out—unfolded—producing the condition shown in C). A, stomach; B, transverse colon; C, small intestine; D, duodenum; E, pancreas; F, great omentum; G, placed in great sac; H, in small sac of peritoneum.

The **great omentum** is, as pointed out above, a bag-like growth of the lower part of the mesogastrium, which passes downwards and to the left in front of the transverse colon. As shown in Fig. 783, A and B, it is first entirely unconnected with the transverse colon and mesocolon; but about the third or fourth month it becomes united to both, and the adult condition is established (Fig. 783, C).

It would appear that the growth of the lower part of the small sac, and of the great omentum, is primarily due to a proliferation of the cells over a limited area of the mesogastrium, and a resulting folding of this layer downwards and to the left.

In the upper part of the mesogastrium the **spleen** is developed, and the portion of

this fold which intervenes between the stomach and spleen forms the gastro-splenic omentum, whilst the part behind the spleen becomes the lieno-renal ligament.

Of the primitive mesentery, the portion connected with the stomach—the mesogastrium—becomes modified in the manner just described. The next division—the mesoduodenum—disappears completely, owing to the turning over of the duodenal loop on to its right side, and its subsequent adhesion to the posterior abdominal wall, accompanied by the absorption of its mesentery. The mesenteries of the small and large intestine are continuous at first (Fig. 781). When the rotation of the intestinal loop takes place around the superior mesenteric artery (see above), the beginning of the large intestine, with its mesentery, is carried to the right across the duodenum, and a fan-shaped portion of the general mesentery, lying within the concavity of the loop, is partially cut off; this, later on, forms the mesentery proper in the adult. At first it is continuous by its right border with the mesentery of the ascending colon, a part of the primitive mesentery (which is similarly continued into the mesentery of the transverse, descending, iliac, and pelvic colons). Subsequently, as shown by the darkly-shaded parts in Fig. 782, the back of the mesenteries of the ascending, descending, and iliac portions of the colon adheres to the posterior abdominal wall, and these mesenteries become lost; whilst the mesenteries of the transverse and pelvic portions of the colon remain free, and persist in the adult.

At the same time, the mesentery proper (which was at first attached only at its narrow neck, between the duodenum and transverse colon, and below this was continuous on the right with the ascending mesocolon) now acquires a new attachment to the posterior abdominal wall through the absorption of the ascending mesocolon (Fig. 782), and the adult condition is attained.

## THE LIVER.

The **liver** (hepar) is a large glandular mass of irregular shape, which lies under cover of the ribs in the upper and right portion of the abdominal cavity, immediately beneath the diaphragm (Fig. 784). It is the largest of all the digestive glands, and plays an important part in the metabolism of both carbohydrate and nitrogenous materials: in addition, it secretes the bile—a fluid which although chiefly excretory, assists to some extent in pancreatic digestion. From the liver the bile is conveyed to the duodenum by the *bile duct*, in connexion with which is found a pear-shaped diverticulum, for the temporary storage of the bile, known as the *gall-bladder* (Fig. 786).

**Form.**—The liver is so irregular, and varies so considerably in size and shape in different bodies, and even in the same body under different conditions, that it is difficult to convey a true idea of its form. This, perhaps, may be most readily realised from a consideration of the portion of the abdomen in which the liver lies, and to the shape of which its form is chiefly due.

The upper portion of the abdominal cavity is dome-shaped, its anterior, posterior, and lateral walls, as well as its roof, being formed chiefly by the vaulted under surface of the diaphragm, which slopes down on the inner aspect of the ribs as far as the lower border of the thoracic framework. In the right and middle portions of the dome-shaped space thus formed the liver lies, like a cast in its mould, and from it chiefly its form is derived. And, if an imaginary plane be passed backwards and upwards, from an oblique line extending across the anterior abdominal wall, from a point immediately below the right margin of the ribs to a point one inch below the left nipple, it will cut off a segment of the abdominal cavity which corresponds tolerably accurately to the liver, in both size and form.

Accordingly, the liver may be described as having two chief surfaces: a *parietal surface*, convex in general outline, which fits into the arch of the diaphragm; and a *visceral surface*, irregular in form, which looks downwards, backwards, and to the left, and rests upon the abdominal viscera. These two surfaces are separated from one another by the *inferior margin* of the liver.

Symington has described the liver, when hardened *in situ*, as a right-angled triangular prism with its right angles rounded off, and as having five surfaces—anterior, posterior, superior, right, and inferior. The first four of these would be included in the parietal surface described above, and the inferior corresponds to the visceral surface.

Previously His had described three surfaces: an inferior, corresponding to the visceral, and a superior and posterior, which together correspond to the parietal surface.

Before His's description, which changed all previous views on the form of the liver, became current, it was described as having two surfaces, an upper and a lower, and two borders, an anterior thin and a posterior thick; and this is the shape of the ordinary soft dissecting-room liver, which flattens out into a cake-like form when removed from the body.

In the body, on the other hand, instead of being flattened out in this way, it is folded, as it were, around its portal and longitudinal fissures into a much more compact mass; and if hardened *in situ* before its removal, it presents an appearance very different from that of the soft liver just referred to. From a study of such hardened specimens it will be seen that the mass of the right lobe lies chiefly in an antero-posterior direction, its posterior thick portion fitting into a wide groove at the side of the vertebral column, and its long axis running from behind forwards and a

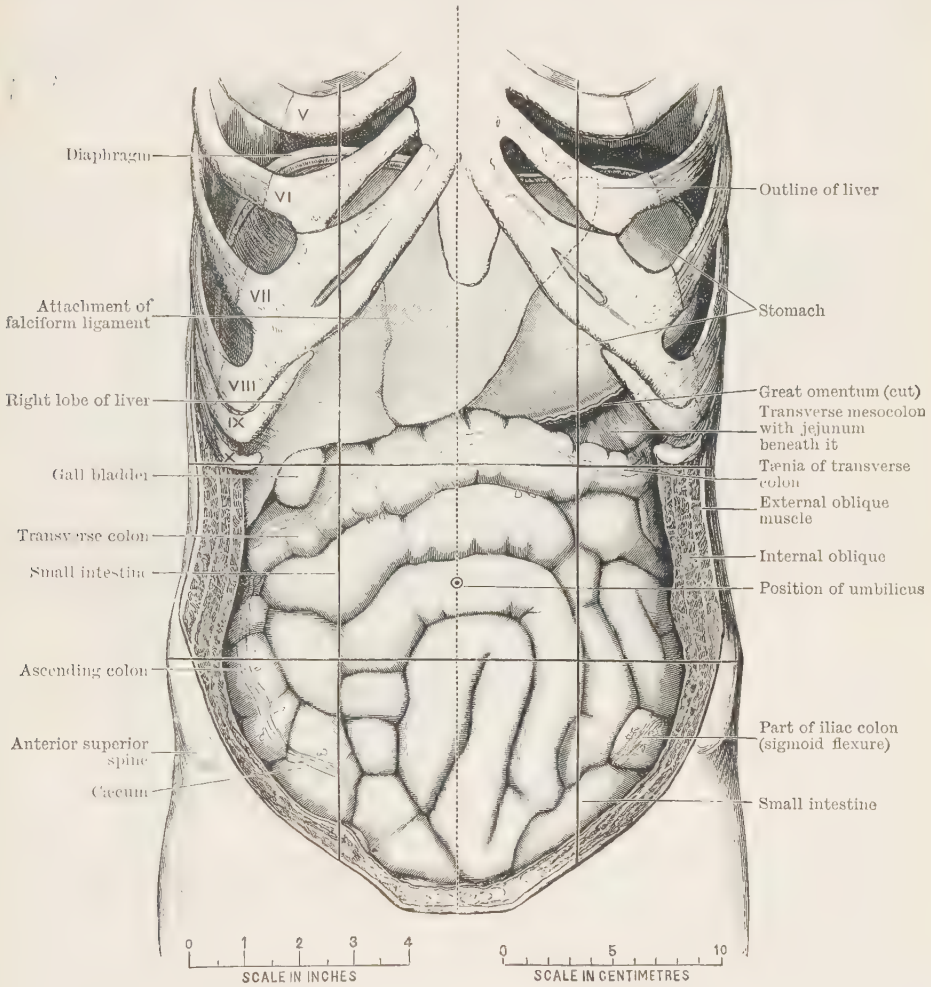

FIG. 784.—THE ABDOMINAL VISCERA IN SITU, as seen when the abdomen is laid open and the great omentum removed (drawn to scale from a photograph of a male body aged 56, hardened by formalin injections).

The ribs on the right side are indicated by Roman numerals; it will be observed that the eighth costal cartilage articulated with the sternum on both sides. The subcostal, intertubercular, and right and left Poupart lines are drawn in black, and the mesial plane is indicated by a dotted line. The intercostal muscles and part of the diaphragm have been removed, to show the liver and stomach extending up beneath the ribs. The stomach was moderately distended, and the intestines were particularly regular in their arrangement.

little inwards. The left lobe, leading off from the anterior part of the right lobe, is folded across the front of the vertebral column and great vessels, its long axis running transversely, but it does not usually pass back at the side of the vertebral column, like the right lobe, into the vertebral groove; so that there is no real notch, as usually described, at the back of the liver for the vertebral column, but merely an angle formed by the meeting of the two lobes coming from different directions.

**Position.**—The main mass of the liver lies in the right hypochondrium; from this it extends across the upper part of the epigastrium, and usually reaches as far as the left Poupart plane. Not uncommonly it passes into the left

hypochondrium, where it may extend even as far as the left lateral wall of the abdomen. Usually, too, its lower margin passes down on the right side for a little distance ($\frac{1}{2}$ inch, 12·5 mm.) below the subcostal plane, and comes to lie in the right lumbar region. Under ordinary conditions, the anterior end of the longitudinal fissure, which separates the right from the left lobe, lies one or two inches to the right of the mesial plane.

The limits even of the normal liver are very variable, but, taking the average condition in the male, they may be marked out on the surface of the body by the following method:—Three points are determined—(*a*) half an inch (12·5 mm.) below the right nipple; (*b*) half an inch (12·5 mm.) below the right margin of the thorax (or below the tip of the tenth rib); and (*c*) one inch (25 mm.) below the left nipple. If these points be joined by three lines, slightly concave towards the liver, they will give the outline of the organ with sufficient accuracy for all ordinary purposes. (For variations in position see p. 1117.)

To state the matter somewhat more in detail:—if the two "nipple points" (*a*) and (*c*) be joined by a line, slightly convex upwards on each side, but a little depressed at the centre corresponding to the position of the heart, and crossing the lower end of the sternum about the level of the sixth cartilage, it will mark the upper limit. A line, convex outwards, from the right nipple point (*a*) to the subcostal point (*b*) will indicate the right limit, while the lower limit is marked by a line, convex downwards, drawn from the subcostal point (*b*) to the left nipple point (*c*), and passing through a point half-way between the umbilicus and the lower end of the gladiolus, in the middle line.

The line indicating the *upper limit of the liver* is elevated on each side, corresponding to the cupolæ of the diaphragm, and depressed in the centre beneath the heart. On the right side where highest, namely, about one inch (25 mm.), internal to the mammary line, it reaches during expiration to the upper border of the fifth rib; on the left side it is one-half to three-quarters of an inch (12 to 18 mm.) lower; and it crosses behind the sternum at the level of the sixth sterno-costal junction—or sometimes lower. It must be remembered, however, that, whilst the liver reaches up to the levels just given, it does so only at the highest part of its convex parietal surface, and is separated from the ribs all round by the thin lower margin of the lung (which extends down between the chest wall and diaphragm to the sixth rib in front, to the eighth in the mid-lateral line, and to the level of the tip of the spine of the tenth dorsal vertebra behind), so that, in percussing over the liver, its dulness is obscured by the resonance of the lungs above these points.

**Weight and Size.**—The liver usually weighs from three to three and a quarter pounds, or about $\frac{1}{40}$th of the body weight.

The average size of the liver may be briefly expressed as follows:—It measures in the transverse direction about seven inches (17·5 cm.); in the vertical, six to seven inches (15 to 17·5 cm.); and in the antero-posterior, on the right side where greatest, about six inches (15 cm.) Its greatest width, measured obliquely from side to side along the inferior or visceral surface, is ten inches (25 cm.)

Its weight ordinarily varies between fifty and fifty-five ounces in the male, and between forty three and forty-eight in the female, with an average for the two sexes of about forty-nine ounces, or a little over three pounds. It corresponds to about $\frac{1}{40}$th of the body weight in the adult; whilst at birth it is relatively twice as large (viz. $\frac{1}{18}$th or $\frac{1}{20}$th of the body weight), and in the early fœtus very much larger.

The proportion of the right to the left lobe is very variable, but is usually about as 4 to 1; at birth it is about as 2 or 3 to 1.

**Relations and Surfaces.**—The liver, as already pointed out, possesses two chief surfaces, the parietal lying in contact with the abdominal parietes, and the visceral resting on the abdominal viscera.

Parietal Surface.—In conformity with the shape of the upper portion of the abdominal cavity which it occupies, the parietal surface (Fig. 785) is convex in general outline, and, taken as a whole, lies against the diaphragm, except below and in front, where it projects from beneath the ribs (Fig. 784), and comes in contact with the anterior abdominal wall for about two or three inches (5·0 to 7·5 cm.) below the xiphi-sternal articulation. It is completely covered by peritoneum, except behind at the "uncovered area," where it comes into direct relation with the diaphragm; and it is divided into right and left lobe-portions by the attachment of the falciform ligament—a fold of peritoneum which connects it to the diaphragm and anterior abdominal wall.

As the space which the liver occupies is bounded by the anterior, the right,

and the posterior walls of the abdomen, as well as by the roof, we can distinguish on its parietal surface, which lies against, and takes its shape from, these walls, four corresponding "areas," namely (*a*) the superior, (*b*) the anterior, (*c*) the right, and (*d*) the posterior areas of the parietal surface. Of these the posterior area is the most important, and must be described in greater detail than the others.

**Posterior Area of the Parietal Surface.** — This portion of the parietal surface (which corresponds to the posterior surface of His) is directed backwards, and lies in contact with the diaphragm, as the latter passes down on the posterior abdominal wall. It is very irregular in shape, and presents from right to left the following parts:—(1) The "uncovered area" of the right lobe; (2) the suprarenal impression; (3) the fossa of the vena cava; (4) the Spigelian lobe, separated by the fissure of the ductus venosus from (5) the œsophageal groove, which belongs to the left lobe.

(1) The "**uncovered area**" of the right lobe (Fig. 786) is a considerable portion

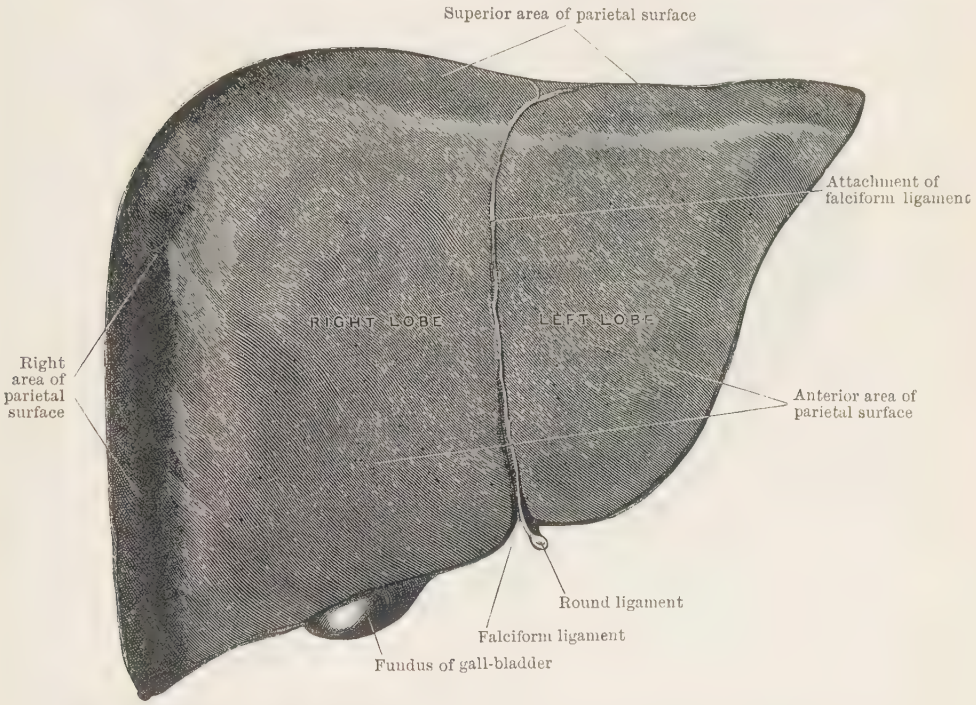

FIG. 785.—THE LIVER FROM THE FRONT, showing the superior, right, and anterior areas of the parietal surface.

of the back of the right lobe—varying from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches (3·7 to 6·2 cm.) in width, and from 3 to 4 inches (7·5 to 10 cm.) in transverse measurement—which corresponds to the interval between the two layers of the coronary ligament, and is devoid of peritoneum. Over this uncovered portion, which looks more inwards than backwards, the liver and diaphragm are in direct contact, and are united by areolar tissue; here too is established a communication by small veins between the portal circulation of the liver and the systemic circulation of the diaphragm.

(2) **Suprarenal Impression.**—On the "uncovered area," immediately to the right of (and behind) the vena cava, is a triangular impression (impressio suprarenalis, Fig. 786), produced by the suprarenal body, which, projecting upwards from the top of the right kidney, becomes wedged in between the diaphragm and liver.

(3) **Fossa of the Vena Cava** (fossa venæ cavæ).—At the left extremity of the "uncovered area" the inferior vena cava lies vertically, embedded in a fossa of the liver substance, between the Spigelian lobe on the left and the adjacent part of the uncovered area on the right, both of which project over the sides of the cava, almost hiding it from view (Fig. 786); sometimes they actually meet and form a **pons hepatis** across the back of the vein.

(4) **Spigelian Lobe.**—To the left of the fossa of the cava lies the Spigelian lobe (lobus caudatus), a prominent oblong mass (Fig. 786), which is placed vertically on the back of the liver, between the fissure of the ductus venosus on the left and the fossa of the vena cava on the right—the former marking it off from the left lobe, the latter from the "uncovered area" of the right lobe. The top of the small sac of peritoneum separates the back of the Spigelian lobe from the diaphragm, which latter, in turn, separates it from the aorta just before that vessel enters the abdomen.

The upper end of the Spigelian lobe is separated from the superior area of the parietal surface by the meeting of the vena cava and the fissure of the ductus venosus in front of it. Its lower

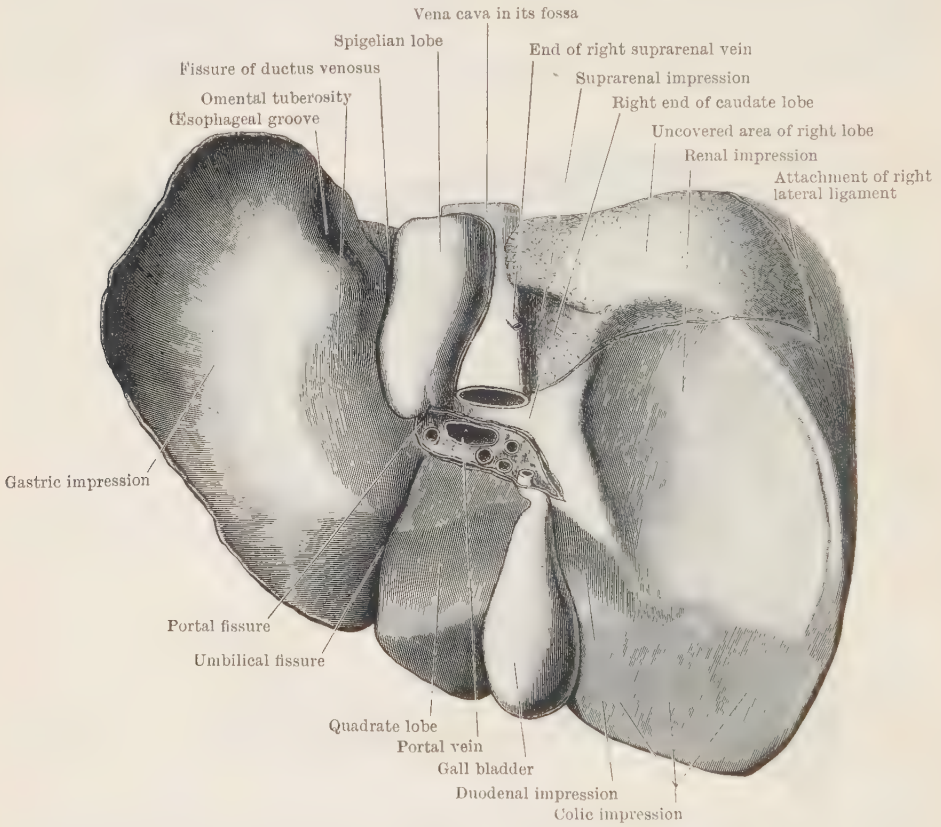

FIG. 786.—THE LIVER FROM BELOW AND BEHIND, showing the whole of the visceral surface and the posterior area of the parietal surface. The portal fissure has been slightly opened up to show the vessels passing through it; the other fissures are represented in their natural condition—closed. In this liver, which was hardened *in situ*, the impressions of the sacculations of the colon are distinctly visible at the colic impression. The round ligament and the remains of the ductus venosus are hidden in the depths of their fissures.

end is free and prominent, and reaches to the visceral surface, where it usually presents a notch or fissure (in which the hepatic artery lies, particularly in the fœtus), which marks off a larger and more prominent left part (the tuberculum papillare) projecting downwards behind the portal fissure, and a smaller right part passing out into the processus caudatus, or caudate lobe which connects it (Fig. 786) with the under or visceral surface of the right lobe.

The posterior surface of the Spigelian lobe is free; it is placed vertically, and looks backwards and slightly inwards. The lobe has also another surface, which is hidden when in the body and, in the hardened liver by the folding of the left lobe across it. By this folding there is formed a deep fissure (fissure of the ductus venosus), at the bottom of which will be found the remains of the ductus venosus.

(5) The **Œsophageal Groove** is situated on the back of the left lobe, to the left of the upper end of the Spigelian lobe, but separated from it by the fissure of the ductus venosus (fossa ductus venosi), which on this aspect indicates the division between the right and left lobes. The groove leads down into the gastric impres-

sion on the visceral surface of the left lobe (Fig. 786), and, when in the body, lies in contact with the prominent right or anterior margin of the œsophageal orifice of the diaphragm (see p. 1040 and Fig. 795), sometimes also with the œsophagus itself.

The **superior area** of the **parietal surface** lies in contact with the roof of the abdomen; it is convex on each side, and depressed near the middle line. The two convexities, of which the right is the more prominent, fit into the two cupolæ of the diaphragm; whilst the central depression (depressio cardiaca) corresponds to the position of the heart. This area (with the exception of a small triangle at its posterior part, between the separating layers of the falciform ligament) is completely covered by peritoneum, and on it the division of the liver into right and left lobes is indicated by the attachment of the falciform ligament.

The **anterior area** of the **parietal surface** is triangular in shape, and after death is usually flattened, owing to the falling in of the anterior abdominal wall. In part it lies in contact with the diaphragm, which separates it from the rib-cartilages on each side, but at the subcostal triangle it comes into direct relation with the anterior wall of the abdomen, for a distance usually of two or three inches below the xiphi-sternal articulation. It has a complete peritoneal covering, and gives attachment as far down as the umbilical notch, at the inferior border, to the falciform ligament, which connects it to the anterior abdominal wall.

The anterior passes gradually into the upper and right areas, but it is distinctly separated from the visceral surface by the sharp inferior border of the organ. The umbilical notch is often continued upwards for some distance on the surface as a slit-like fissure.

The **right area** of the **parietal surface** is convex and extensive, and lies in contact with the diaphragm, which separates it from the inner surface of the lower ribs, and also from the lower margin of the lung and pleura above. Though sharply marked off by the inferior border from the visceral surface, it passes without distinct limits into the other areas of the parietal surface. It is completely covered by peritoneum.

**Visceral or Inferior Surface.**—This is an irregular, obliquely sloping surface (Fig. 786), which looks downwards, backwards, and to the left, and rests upon the stomach, small omentum, intestines, and right kidney. The division into right and left lobes is indicated on this surface by the umbilical fissure, which passes from the umbilical notch at the anterior border back to the portal fissure.

The visceral surface of the *left lobe* is directed downwards and backwards, and rests on the upper surface of the stomach, in front of the cardia; also on the lesser curvature with its attached lesser omentum. The part which rests upon the upper surface of the stomach is rendered concave by the pressure of that organ (Fig. 786), and is known as the **gastric impression** (impressio gastrica); whilst the portion to the right of this, being free from the pressure of the stomach, projects backwards over the lesser curvature against the lesser omentum in the form of a smooth rounded prominence, and is known as the **omental tuberosity** (tuber omentale).

The visceral surface of the *right lobe* may be divided into two portions by the line of the gall-bladder, which extends forwards in its fossa to the lower sharp margin of the liver (Fig. 786).

(**a**) *To the left of the line of the gall-bladder* are found from before backwards:—The quadrate lobe, portal fissure, and caudate lobe. (1) The **quadrate lobe** (lobus quadratus) is placed at the anterior part of the under surface, between the gall-bladder and the umbilical fissure, extending to the inferior margin of the liver in front, and to the portal fissure behind: it rests upon the pylorus or the beginning of the duodenum. (2) The **portal** or **transverse fissure** is a deep cleft through which the portal vein, hepatic artery, and hepatic duct enter the liver, and to the margins of which are attached the two layers of the lesser omentum (Fig. 786). (3) The **caudate lobe** or **process** (processus caudatus) consists of a narrow ridge of liver substance which runs across behind the portal fissure, and connects the lower end of the Spigelian lobe with the rest of the right lobe. It forms the upper boundary of the foramen of Winslow, and is felt when the finger is introduced into that passage. It is often very narrow but can always be distinguished through its intervening between the portal vein and the inferior vena cava.

(**b**) *The surface to the right of the gall-bladder,* which is more extensive than that on its left, is entirely occupied by three impressions produced by the underlying viscera—namely: (1) The **colic impression** (impressio colica) lies in front and to the right of the gall-bladder. It rests upon the hepatic flexure and the beginning of the transverse colon. (2) Behind this is the **renal impression** (impressio renalis), larger than the preceding, which corresponds in size and form to

the upper half or two-thirds of the right kidney, against the anterior or visceral surface of which it lies. It is placed behind the colic impression just as the kidney itself is placed behind the colon. (3) To the inner side of the renal impression, and near the neck of the gall-bladder, is placed the narrow **duodenal impression** (impressio duodenalis), which lies in contact with the duodenum (the second part, down to the point at which it is crossed by the colon).

The **quadrate lobe** is of an oblong shape, the antero-posterior diameter being the greatest. Its surface is generally concave, and is related to the pylorus and the adjacent parts of the stomach and duodenum, when the former is distended. When the stomach is empty, however, the pylorus usually lies beneath the right portion of the left lobe, and the first part of the duodenum lies beneath the quadrate lobe, the transverse colon also coming in contact with it anteriorly (Fig. 786).

The upper end of the renal impression is frequently uncovered by peritoneum (Fig. 786), that is to say, the "uncovered area" of the right lobe extends down over the impression for a little way. This impression is very deep, and accommodates nearly the whole thickness of the kidney. In many hardened specimens it would appear to belong more to the posterior part of the parietal than to the inferior or visceral surface.

The **inferior margin of the liver**, as already pointed out, separates the parietal from the visceral surface. *Behind*, it is indistinctly marked and corresponds to the lower edge of the posterior area, or back, of the parietal surface: it is in contact with the right kidney, and runs along the course of the eleventh rib. *At the right side* it is stout but distinct, and usually corresponds to, or projects a little way below, the lower border of the thoracic framework. *In front* (margo anterior) it is thin and sharp, and crosses the anterior abdominal wall obliquely, generally corresponding to a line drawn from a point half an inch (12 mm.) below the margin of the ribs (tip of tenth costal cartilage) on the right side to a point an inch below the nipple on the left, and extending down in the middle line to a point half-way between the gladiolus and the umbilicus. This portion of the lower border usually, but not invariably, presents one or two notches. The **umbilical notch** (incisura umbilicalis), the more constant of the two (Fig. 785), is situated at the anterior end of the umbilical fissure, and corresponds to the lower part of the attachment of the falciform ligament. It is usually placed from one to two inches (2·5 to 5·0 cm.) to the right of the middle line. The second notch, less frequently present, corresponds to the fundus of the gall-bladder, and may be called the **notch of the gall-bladder** (incisura vesicæ felleæ).

At its left extremity the inferior margin passes backwards around the edge of the left lobe, and ends at the œsophageal groove on its back.

**Fissures of the Liver.**—Five fissures or fossæ are usually described in connexion with the liver; these are: (1) the umbilical fissure, (2) the fissure of the ductus venosus; (3) the portal fissure; (4) the fissure, or fossa, of the gall-bladder; and (5) the fissure, or fossa, of the vena cava.

Taken together, the five fissures are arranged somewhat in the form of the letter A (Fig. 786); the two lower divisions of the diverging limbs being formed by the umbilical fissure and the fissure of the gall-bladder respectively, and the cross-piece by the portal fissure —all of which are placed on the inferior or visceral surface. The two upper divisions of the limbs are represented by the fissure of the ductus venosus and that of the vena cava, which meet above and are both placed on the back or posterior area of the parietal surface. The latter of these two—namely, the fissure of the cava, represented by the right upper division of the A—does not join the cross-piece (the portal fissure), but is separated from it below by a narrow ridge of liver substance—the caudate lobe or process (Fig. 786).

(1) The **umbilical fissure** (fossa venæ umbilicalis) is a deep crevice-like fissure, situated on the visceral surface between the adjacent portions of the quadrate and left lobes. At its bottom is seen a stout fibrous band, the round ligament—the remains of the umbilical vein of the fœtus. The fissure leads from the umbilical notch at the inferior border of the liver to the left extremity of the portal fissure (Fig. 786), and is very often crossed by a **pons hepatis**—a band of liver substance —which may even extend along the whole length of the fissure, hiding the round ligament completely from view.

(2) The **fissure of the ductus venosus** (fossa ductus venosi) lies on the back of

the parietal surface of the liver and separates the Spigelian from the left lobe (Fig. 786). It joins the portal fissure below, opposite the umbilical fissure; and above, it meets the fissure of the vena cava. On separating its sides there is found at its bottom a fibrous band, usually much thinner than the round ligament: this is the remains of the ductus venosus of the fœtus.

The umbilical fissure and the fissure of the ductus venosus taken together constitute the **longitudinal fissure of the liver** (fossa longitudinalis sinistra), which separates the right from the left lobe on both the inferior and posterior aspects. It will be observed that all other fissures and all other lobes (except the left) lie to the right of the longitudinal fissure, and therefore are situated on the right lobe.

(3) The **portal or transverse fissure** (porta hepatis) when examined in the unhardened liver appears as a deep depression, bounded by prominent lips, which runs to the right, from the middle of the longitudinal fissure, between the quadrate lobe in front and the caudate and Spigelian lobes behind (Fig. 786). Through it the portal vein, hepatic artery, and hepatic plexus of nerves enter, and the hepatic ducts and lymphatic vessels leave, the liver, whilst around its margins are attached the two layers of the lesser omentum. The fissure itself is filled, between the entering and issuing vessels, by a loose connective tissue known as Glisson's capsule, which passes with the portal vein into the liver substance.

When the liver is in the body, or when hardened before removal, these three fissures, instead of appearing as wide, shallow depressions, have the form of narrow clefts, with a depth of three-quarters to one inch (18-25 mm.), or even more—a form which results from the folding together of the portions of the liver bounding these fissures.

(4) The **fossa of the gall bladder** (fossa vesicæ felleæ) is a slight depression which begins (often as a notch) at or near the inferior border of the liver, and runs backwards and to the left, as far as the portal fissure (Fig. 786), separating the quadrate from the rest of the right lobe. Its surface is uncovered by peritoneum as a rule, and in it lies the gall-bladder—the two being united by areolar tissue.

(5) The **fossa of the vena cava** (fossa venæ cavæ) is a deep groove, on the back of the liver, between the Spigelian and right lobes, in which the upper part of the inferior vena cava is embedded, immediately before it pierces the diaphragm. It has been already described in connexion with the posterior area of the parietal surface of the liver, page 1111.

The depressions for the gall-bladder and the vena cava are called, almost indiscriminately, fissures or fossæ. In hardened specimens, it will be seen that only three are really fissure or crevice-like, namely, the umbilical fissure, the portal fissure, and the fissure of the ductus venosus: the remaining two are rather of the nature of fossæ.

**Lobes of the Liver.**—The liver is divisible into two chief lobes, right and left, which are separated by the attachment of the falciform ligament above and in front, and by the two parts of the longitudinal fissure below and behind. The right lobe forms about four-fifths of the mass of the liver, and on it three secondary lobes—the quadrate, Spigelian, and caudate, already sufficiently described—are marked off by the five fissures referred to in the preceding paragraphs. The left lobe is much smaller and more flattened than the right, and, as a rule, it projects one or two inches (2·5 to 5·0 cm.) to the right of the middle line. The details of these lobes have been already given in connexion with the surfaces of the liver.

**Peritoneal Relations of the Liver.**—With the exception of (1) the uncovered area at the back of the right lobe, (2) a small triangular space on the parietal surface, where the two layers of the falciform ligament separate posteriorly, and (3) usually, but not invariably, the fossa of the gall-bladder, the liver is completely covered by peritoneum. The covering of the caudate and Spigelian lobes is derived from the small sac, that of the rest of the organ from the great sac of the peritoneum.

The peritoneum of the anterior abdominal wall passes back on the under surface of the diaphragm, whence it is reflected on to the upper aspect of the liver, but the line of reflection is broken by a fold running down at right angles from its middle to the umbilical notch; this is the falciform ligament already referred to. The portion of the reflection to the right of this fold forms the upper layer of the coronary ligament, that to the left forms the upper layer of the left lateral ligament.

Having thus reached the liver from the diaphragm, the peritoneum passes forwards, clothing its parietal surface as far as the anterior margin, around which it turns to gain the lower or visceral surface. This it also covers as far back as the portal fissure and the fissure of the ductus venosus (Fig. 786), from which it descends to the stomach as the anterior layer of the lesser omentum.

As regards the covering derived from the small sac:—Its peritoneum passes in through the foramen of Winslow, which is placed immediately beneath the caudate lobe, and thus it clothes this lobe (Fig. 786). Then turning upwards it expands over the Spigelian lobe, clothing its two surfaces.

From the right margin of the Spigelian lobe it is reflected to the diaphragm, here forming the last boundary (Fig. 795) of the uncovered area of the right lobe, and a third layer of the coronary ligament.

The detailed arrangement of the peritoneum will be found on p. 1097, with the general account of the peritoneal cavity.

**Ligaments.** Most of the ligaments of the liver, namely, the coronary, falciform, and two lateral, are formed by folds of peritoneum; the other two, namely, the round ligament and the ligament of the ductus venosus, are remains of fœtal blood-vessels.

The **coronary ligament** (ligamentum coronarium hepatis) consists of the folds of peritoneum which are reflected from the liver to the diaphragm at the margins of the uncovered area of the right lobe; both its upper and lower layers are derived from the great sac. The name of **right lateral ligament** has been given, without sufficient reason, perhaps, to its pointed right extremity (Fig. 786).

The **left lateral ligament** (ligamentum triangulare) is a considerable triangular fold, entirely unconnected with the coronary ligament, which is attached by one end to the upper or parietal surface of the left lobe near its posterior border, and by the other to the diaphragm, for a distance of several inches as a rule.

Its attachment to the diaphragm lies nearly altogether to the left of the œsophageal orifice, and about $\frac{3}{4}$ inch (18 mm.) in front of the line of this opening. Sometimes it is directed from the diaphragm backwards to its hepatic attachment.

**Falciform Ligament** (ligamentum falciforme hepatis).—This is also known as the broad or the suspensory ligament. It is a crescentic fold of peritoneum, which is attached by its convex border to the under surface of the diaphragm, and to the anterior abdominal wall (an inch or more to the right of the middle line) to within a short distance (1 to 2 inches, 2·5 to 5 cm.) of the umbilicus. Its concave border is attached to (the superior and anterior areas of) the parietal surface of the liver; below this it presents a free edge, stretching from near the umbilicus to the umbilical notch of the liver, and containing within it a stout fibrous cord, the round ligament.

Near the back part of the upper aspect of the liver the two layers of which the falciform ligament is composed separate, and leave a triangular area of liver substance in front of the upper end of the vena cava uncovered by peritoneum. Traced backwards, the right layer passes into the upper layer of the coronary ligament, the left into that of the left lateral ligament. It is the remains of the ventral mesentery of the embryo, and has no supporting or suspensory action on the liver of the adult.

The **lesser** or **gastro-hepatic omentum** (omentum minus) is a fold of peritoneum which extends from the liver to the lesser curvature of the stomach. Of its two layers—which are largely blended together in the adult—the anterior is derived from the great, the posterior from the small sac.

It is attached above to the margins of the portal fissure, and also to the bottom of the fissure of the ductus venosus. Below, it is connected to the lesser curvature of the stomach, where its two layers separate to enclose that organ, and also to the upper border of the duodenum for an inch or more beyond the pylorus. Between its layers, close to its right or free border, are contained the bile duct, the hepatic artery, the portal vein, and the nerves and lymphatics passing to the portal fissure (Fig. 788). It is wide in the middle and narrow at each end. Of the two ends the right is free, and stretches from the liver to the duodenum, forming the anterior boundary of the foramen of Winslow. The left end is very narrow, and is attached to the diaphragm between the œsophageal and caval openings (just to the right of the reference line in Fig. 795, marked "top of small sac.")

The portion of the omentum passing between the liver and the stomach is sometimes known as the hepato-gastric ligament (ligamentum hepato-gastricum), that between the liver and the duodenum as the hepato-duodenal ligament (ligamentum hepato-duodenale).

The **round ligament** (ligamentum teres hepatis) is a stout fibrous band which passes from the umbilicus backwards and upwards, within the free margin of the falciform liga-

ment, to the umbilical notch of the liver, and thence back in the umbilical fissure, to join the left branch of the portal vein. It is the remains of the umbilical vein which, before birth, carries the arterial blood from the placenta to the body of the fœtus (Fig. 787).

The **remains of the ductus venosus** (ligamentum venosum Arantii) is a slender fibrous cord, which passes from the left branch of the portal vein, nearly opposite the attachment of the round ligament, backwards in the fissure bearing its name, to be connected with the inferior vena cava as it leaves the liver. In the fœtus this structure is a considerable vessel, which conveys some of the blood brought to the portal fissure by the umbilical vein directly backwards to the vena cava. At the time of birth the ductus venosus and umbilical vein cease to carry blood, their cavities become obliterated, and they degenerate into fibrous cords.

**Physical Characters of the Liver.**—The liver is a compact mass, moderately firm to the touch; it is pliant, but not tough, and is easily lacerated. Its torn surface presents a granular appearance, due to the fact that it is made up of small lobules about the size of a pin's head ($\frac{1}{12}$th to $\frac{1}{25}$th of an inch, 1 to 2 mm.). These little lobules also give its exterior a characteristic finely-mottled appearance. Its colour is reddish brown, and its specific gravity varies from 1·05 to 1·06.

**In the Child.**—The liver of the child differs from that of the adult, in being relatively larger—$\frac{1}{18}$th of the body weight at birth as against $\frac{1}{36}$th or $\frac{1}{40}$th in the adult—in occupying more of the abdominal cavity, and in the fact that its two lobes are more nearly equal in size, the proportion being as two to one at birth and as four to one in the adult.

**Variations in Size, Form, and Position.**—Few organs will be found to vary more in **size** in different bodies than the liver; these variations, however, are very frequently to be looked upon as pathological. But even the normal, healthy liver may vary in weight from 48 to 58 ounces in the adult male, and from 40 to 50 ounces in the female.

**Variations in form** and **position** doubtlessly take place physiologically, as a result of the conditions of fulness or emptiness of the adjacent viscera; for, though the liver, like the other solid abdominal organs, has an intrinsic shape of its own, this is capable of modification within certain limits by the varying pressure of the surrounding parts. Thus, distension of the stomach, or of a portion of the transverse colon lying in the stomach chamber, may push the liver over to the right, so that it may hardly reach the middle line, and at the same time it increases its vertical depth. On the other hand, a distended state of the small intestines, with a contracted stomach and colon, may have the opposite effect, flattening it from below upwards and enlarging it in the transverse direction.

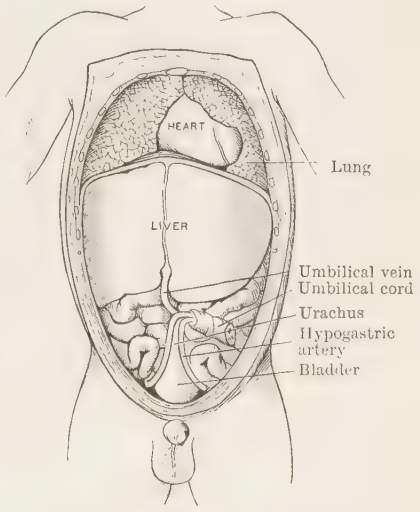

Fig. 787.—The Abdominal and Thoracic Viscera of a Five-Months Fœtus.

The large liver and the large size of its left lobe, at this age, should be noted.

Variations in form and position *due to malformations* of the thoracic framework, either congenital or acquired, are very common, particularly in females as a result of tight-lacing, which carries in the lower ribs. Sometimes in these cases the constriction of the waist lies chiefly below the liver. The organ is then forced up against the diaphragm, filling its whole vault, and extending across to the left abdominal wall, where its left margin may lie in the interval between the diaphragm and the spleen. But more commonly it would seem that the liver is caught by the constriction: its upper part is then closely pressed into the vault of the diaphragm, which, owing to the narrowing of the thorax, is unable to accommodate the whole organ, so that its lower part is crushed down for a considerable distance into the umbilical zone of the abdomen (Fig. 748, p. 1057), particularly on the right side. Often, too, a wide, tongue-like process (the so-called "Reidal's lobe") descends from the lower margin, external to the gall-bladder. This process, which when very large may reach to the iliac crest, is sometimes found in men, although more common in women, and is liable to be mistaken for a tumour. A somewhat similar process occasionally descends from the left lobe.

Again, in apparently healthy bodies the liver may extend up on the right side almost to the fourth rib; whilst in other cases it may be as low as the sixth rib, or even lower. Nor is it rare—particularly in females—to find the lower border projecting two or three inches (5·0 to 7·5 cm.) below the margin of the thorax on the right side (Fig. 748, p. 1057).

Reference should be made here to certain grooves often seen on the liver. Some of these are found running obliquely low down at the right side where the liver is in contact with the ribs;

they are particularly common in females, and are due to the pressure of the ribs resulting from tight-lacing. Grooves of a different kind are found at the upper part of the parietal surface; where the liver is in contact with the diaphragm; these usually run radially, that is, in the direction of the muscular fibres of the diaphragm, and are apparently produced by a wrinkling, or irregular contraction, of the diaphragm. At least, ridges of the diaphragm are found lying in the grooves, and these ridges or wrinkles would seem to be responsible for the production of the grooves.

Finally, the liver may present certain **congenital irregularities** in the direction of additional fissures and lobes, which reproduce the conditions found in the higher apes, and are very commonly present in the fœtus (Thomson). Or the liver may be divided up into a large number of distinct lobes, as in most other animals.

**Changes in position** have been already referred to in connexion with variations in form; there need only be added here that the liver ascends and descends at every expiration and inspiration respectively, and that it also descends, but very slightly, in changing from the reclining to the erect posture. Occasionally, without any evident cause, the liver and diaphragm are found to occupy a higher or lower position than usual.

**Fixation of the Liver.**—At first sight it is not easy to understand the means by which the liver maintains its position in the abdomen (and the same remark applies, perhaps, to other solid abdominal organs). The falciform ligament gives it no support, as it is quite lax when in the body. Nor can it be said that its vessels, except perhaps the hepatic veins, assist. However, on considering the conditions under which the viscera are placed in the abdominal cavity the problem becomes less difficult.

The abdomen is a closed cavity, with a firm framework to its upper part, a tightly stretched diaphragm for its roof, and muscular walls all round. Into the concavity of this roof the parietal surface of the liver is fitted with perfect accuracy, so that the two are in absolute contact, and cannot be separated without producing a vacuum, unless some other structure is in a position to fill the space. But there is hardly any other viscus movable enough to pass up over the front of the liver into the vault of the diaphragm, so that atmospheric pressure alone is probably sufficient to retain the organ *in situ*, as in the case of the hip joint. In addition, the abdominal muscles are always in a condition of tonic contraction or "tone," which gives rise to an intra-abdominal pressure. This is effective in all directions, and consequently there is a considerable pressure on all the abdominal walls. The liver, being in absolute contact with the roof, may be considered a part of this wall, and it is consequently affected by this pressure which helps to sustain it. Add to this, the support which the organ receives from the intestines, the stomach, and the pancreas; from the coronary and lateral ligaments; from the connexion of the back of the right lobe by areolar tissue to the diaphragm; and, finally, from the vena cava embedded in the liver and sending its hepatic veins forwards to all parts of the organ, just before the cava itself is firmly attached to the margins of the caval orifice in the central tendon of the diaphragm, and we will probably find sufficient cause for the maintenance of the organ in its position in the abdominal cavity.

## THE GALL-BLADDER AND BILE-PASSAGES.

Under this heading we have to consider the hepatic ducts, the gall-bladder, the cystic duct, and the common bile-duct.

The **excretory ducts** of the liver (Fig. 788) begin within the hepatic lobules as minute channels, running between the hepatic cells (Fig. 792), and known as the **bile canaliculi** (ductus biliferi).

Outside the lobules these join (Fig. 792) the **interlobular ducts** (ductus interlobulares), which latter by uniting form larger and larger ducts, and finally end in two, or more, chief hepatic ducts, a larger from the right, and a smaller from the left lobe, which unite immediately after leaving the liver to form the hepatic duct.

As a rule, five or six ducts leave the liver at the bottom of the portal fissure; these generally unite into right and left main ducts; sometimes they all converge towards, and unite at the beginning of the hepatic duct. It is interesting to note that the ducts from the Spigelian and caudate lobes join the left main duct.

**Hepatic Duct** (ductus hepaticus).—This duct formed at the bottom of the portal fissure by the union of right and left chief ducts (Fig. 788), passes downwards, with an irregular course, and, just outside the mouth of the portal fissure, is joined by the cystic duct (Fig. 788) to form the common bile-duct. In length it usually measures about 1 to $1\frac{1}{4}$ inches (25 to 31 mm.), and in breadth, when flattened out, nearly $\frac{1}{4}$ inch (6 mm.), or about as much as a goose quill. It lies, practically altogether, within the portal fissure.

**Gall-bladder** (vesica fellea).—The gall-bladder, with its cystic duct, may be looked upon as a diverticulum of the bile-duct, enlarged at its extremity to form a reservoir for the bile. It is pear-shaped, and lies obliquely on the under surface of

the liver (Fig. 788). The wide end, or **fundus**, usually reaches the inferior border of the liver—where there is sometimes a notch to receive it—and comes in contact with the anterior abdominal wall (Fig. 784). The **body** (corpus) runs backwards, upwards, and to the left, lying in the fossa of the gall-bladder, and near the portal fissure passes rather abruptly into the narrow neck. The **neck** (collum) is curved inwards towards the portal fissure, in the form of the italic letter *s*, and when distended it presents the appearance of a spiral constriction which is continued into the beginning of the cystic duct, and is due to a series of crescentic folds placed somewhat spirally round the interior of its cavity. Having arrived near the portal fissure, much reduced in size, it passes into the cystic duct.

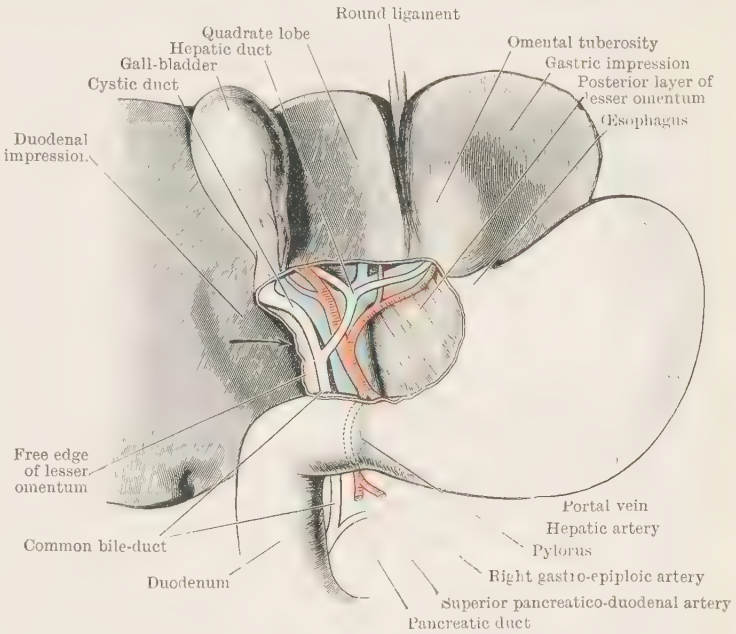

FIG. 788.—STRUCTURES BETWEEN THE LAYERS OF THE LESSER OMENTUM.
The liver has been raised up, and the anterior layer of the omentum removed (semi-diagrammatic).

As a rule the gall-bladder is covered by the peritoneum of the inferior surface of the liver, except on its upper aspect, which is united to the fossa of the gall-bladder by areolar tissue. Sometimes, but rarely, this surface is covered also, and the gall-bladder is then suspended from the liver by a short peritoneal ligament. The fundus usually lies in contact with the anterior abdominal wall, at or immediately beneath the point where the right Poupart line strikes the lower margin of the ribs (*i.e.* in the angle between the outer border of the right rectus muscle and the lower margin of the ribs). *Above*, the gall-bladder lies against the liver; and *below*, it rests on the transverse colon in front, and behind, near its neck on the duodenum.

In some bodies the fundus of the gall-bladder does not reach the border of the liver or the abdominal wall. In others it may be moved considerably to the right of the Poupart line—possibly as a result of distension of the stomach and colon—or as a result of tight-lacing, it may be moved to the left, and may then lie near the middle line and far below the ribs (Fig. 748, p. 1057).

Its total absence, as well as the presence of two distinct gall-bladders, and several other irregularities in form, have been recorded.

Its *size* is usually about 3 inches (75 mm.) in length, and 1 to $1\frac{1}{4}$ inch (25 to 31 mm.) in diameter. Its capacity varies between 1 and $1\frac{1}{2}$ fluid ounces.

**Structure of Gall-bladder.**—The wall of the gall-bladder is composed of an outer coat of peritoneum, usually incomplete; a middle coat of fibrous tissue with unstriped muscle intermixed; and an inner coat of mucous membrane, which is covered by columnar epithelium, and is raised into a number of small ridges, which confer on it a reticulated appearance. The mucous membrane is always deeply stained with bile when the gall-bladder is opened after death.

The **cystic artery** which supplies it with blood arises from the hepatic, or its right division, and divides into two branches, which run on the lateral surfaces of the organ. The **veins** join the portal trunk, and the **nerves** come from the sympathetic on the hepatic artery.

The **cystic duct** (ductus cysticus), about half the diameter of the hepatic duct (3 mm.), but usually slightly longer ($1\frac{1}{4}$ to $1\frac{1}{2}$ inch, 31 to 37 mm.), begins at the

neck of the gall-bladder, and running an irregular course backwards and inwards, joins the hepatic duct at the mouth of the portal fissure, to form the common bile-duct. The spiral constriction found in the neck of the gall-bladder is continued into the beginning of this duct.

Sometimes the cystic duct joins the right hepatic duct instead of the hepatic duct proper.

**Common Bile-duct** (ductus choledochus). This begins at the mouth of the portal fissure, where it is formed by the union of the hepatic and cystic ducts. From this it passes downwards, in front of the foramen of Winslow, lying between the two layers of the lesser omentum, with the portal vein behind and the hepatic artery to its left. It next descends behind the first part of the duodenum (Fig. 788), and then between the pancreas and descending duodenum. Finally, it meets the pancreatic duct, and the two, running together, pierce the inner wall of the descending duodenum very obliquely, and open by a common orifice on the bile papilla (papilla duodenalis), about $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.) beyond the pylorus (see p. 1069).

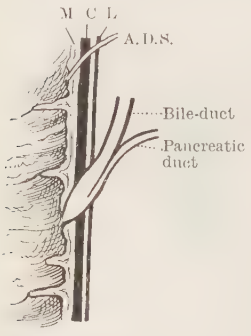

Fig. 789.—Diagram showing the Bile and Pancreatic Ducts piercing the Wall of the Duodenum obliquely.

A.D.S, Accessory pancreatic duct (of Santorini); C, Circular muscular fibres; L, Longitudinal muscular fibres; M, Mucous coat.

The length of the common bile-duct is about 3 inches (75 mm.), and its diameter, which is very variable, is generally about $\frac{1}{4}$ inch (6 to 7 mm.).

**Structure of Excretory Ducts.**—With the exception of the peritoneal coat, which is absent, the hepatic, cystic, and common bile-ducts agree with the gall-bladder in general structure.

The bile and pancreatic ducts, in piercing the wall of the duodenum, run obliquely through its coats for about $\frac{1}{2}$ or $\frac{3}{4}$ of an inch (12 to 18 mm.), and, as a rule, do not unite until they have almost reached the opening on the bile papilla (Fig. 789). This orifice is very much smaller than either duct, and the short and relatively wide common cavity which precedes it is sometimes known as the "ampulla of Vater." Occasionally the cystic and hepatic ducts open into the duodenum separately.

### Vessels of the Liver.

The liver derives its blood-supply from two sources, namely—(1) the **portal vein**, which conveys to it, for further elaboration, the blood from the digestive system, laden with the products of digestion; and (2) the **hepatic artery**, which supplies it with blood for the nourishment of its own tissue. All the blood is returned from the liver to the inferior vena cava by the **hepatic veins**.

The **portal vein** and the **hepatic artery** pass up to the liver between the two layers of the lesser omentum and in front of the foramen of Winslow. Here they are accompanied by the hepatic duct, which lies to the right, whilst the artery is placed to the left, and the portal vein behind both. In this order they enter the portal fissure, and there becoming re-arranged, so that the vein lies behind the artery in the middle and the duct in front, each breaks up into two chief branches—a right and a left—and several smaller ones, which enter the liver substance, surrounded by a prolongation of the connective tissue coat of the liver, known as Glisson's capsule. Within the organ the three vessels run and divide together, so that every branch of the portal vein is accompanied by a corresponding (but much smaller) branch of the hepatic artery and of the hepatic duct: and the three, surrounded by a prolongation of Glisson's capsule, and accompanied by branches of the hepatic nerves and lymphatics, run in special tunnels of the liver substance, which are known as **portal canals** (Fig. 791, B).

Finally, the portal vein breaks up into **interlobular veins** (venæ interlobulares) which lie in the spaces between the liver lobules (Fig. 792). The branches of these enter the lobules on all sides, and unite with their capillary network, which converges towards the centre of the lobule, and joins the intralobular or central vein (vena centralis).

The hepatic artery similarly divides into **interlobular branches** (rami arteriosi interlobulares) of a very small size, which accompany the interlobular branches of the vein, and supply the tissue and the vessels between the lobules. In addition, the hepatic artery gives off **vaginal branches** to supply the walls of the vessels and ducts, and the

connective tissue in the portal canals; and **capsular branches**, which are distributed to the fibrous coat of the liver.

The **hepatic veins** are two large and several small veins, which converge from the different portions of the liver (Fig. 791, A) to the vena cava. Their ultimate radicles are the intralobular or central veins, which run down through the centre of the liver lobules, and passing out at the base, join the **sublobular veins** (Fig. 790): these by their union finally form the hepatic veins. The two chief hepatic veins, which are of very large size, open into the vena cava, as it leaves the liver, and immediately before it pierces the diaphragm. The smaller branches open into it lower down. The branches of the portal differ from those of the hepatic vein in the following points:—(1) The branches of the portal vein converge towards the portal fissure; those of the hepatic veins towards the vena cava. (2) On section of the liver the portal branches are always seen to be accompanied by branches of the hepatic artery and duct, whilst those of the hepatic vein run alone; and (3) owing to the loose wrapping of connective tissue (Glisson's capsule) which surrounds the branches of the portal vein, their walls fall away from the liver substance when empty, and collapse, whilst the hepatic veins, which are destitute of this wrapping, are closely connected to the liver substance, and consequently do not collapse so easily as the portal vessels.

The **lymphatics** of the liver are arranged in a superficial and a deep set:—1. The **superficial set** lies beneath the peritoneum on both (*a*) the visceral and (*b*) the parietal surfaces of the organ. (*a*) The vessels from the *visceral surface* pass chiefly to the hepatic glands, which lie between the layers of the lesser omentum; but some of them, from the back part of this surface on the right lobe, join the lumbar glands, and others from the back part of the left lobe go to the cœliac glands. (*b*) The vessels from the *parietal surface* pass in various directions. Those from the adjacent parts of the right and left lobes pass up in the falciform ligament, and pierce the diaphragm to reach the anterior mediastinal glands, and end finally in the right lymphatic duct. Those from the anterior part of this surface pass down to the inferior aspect, and join the hepatic glands in the lesser omentum. The lymphatics from the back of the right lobe pierce the diaphragm between the layers of the coronary ligament, and join some glands in the thorax around the upper end of the inferior cava; others run in the right lateral ligament, and either pierce the diaphragm and end in the anterior mediastinal glands, or, turning down, join the cœliac group.

2. The **deep lymphatics** accompany either (*a*) the portal or (*b*) the hepatic veins. (*a*) The former set pass out through the portal fissure and join the hepatic glands, the efferent vessels of which join the cœliac glands. (*b*) Those which accompany the hepatic veins pierce the diaphragm with the vena cava, and having formed connexions with the group of glands at its upper end, within the thorax, turn down and join the beginning of the thoracic duct.

The **nerves**, which are chiefly of the non-medullated variety, are derived from the left pneumogastric and the solar plexus of the sympathetic. The branches of the former pass from the front of the stomach up between the layers of the lesser omentum to the liver. Those of the latter pass from the cœliac plexus along the hepatic artery—forming the hepatic plexus—to the portal fissure, where they enter the liver with the blood-vessels. They are distributed chiefly to the walls of the vessels and of the bile-ducts.

## Structure of the Liver.

The liver is invested by an outer **serous coat** (tunica serosa), already described in connexion with the peritoneum. Within this is a thin **areolar coat** (capsula fibrosa Glissonii) of delicate fibrous tissue, which is most evident where the serous coat is absent. In the neighbourhood of the portal fissure it is particularly abundant, and here, under the name of **Glisson's capsule**, it surrounds the vessels entering the fissure, and accompanies them through the portal canals in the liver substance. This coat is continuous with the fine areolar tissue which pervades the liver, surrounding its lobules and holding them together.

The liver substance proper is made up of an enormous number of small lobules, $\frac{1}{12}$th to $\frac{1}{25}$th inch (1 to 2 mm.) in diameter, closely packed, and held together by a small amount of connective tissue. In man the lobules are not completely separated from one another all round their circumference, but coalesce in places; the reverse is the case in certain animals such as the camel and the pig. The lobules are arranged around the branches of the hepatic veins, to form the compact mass of the liver, in the following manner:—

The hepatic veins radiate from the inferior vena cava, at the back of the liver, to all parts of the organ, dividing and re-dividing until the vessels are reduced to branches of a very small size, known as **sublobular veins**—the whole arrangement may be aptly compared so far to the branching of a tree (Fig. 791, A). On all sides there open into these sublobular veins numerous closely-crowded vessels—the **intralobular or central veins**

(which, following our simile, may be compared to an enormous number of thorns growing out on all sides from the sublobular twigs of the tree). On each of these little

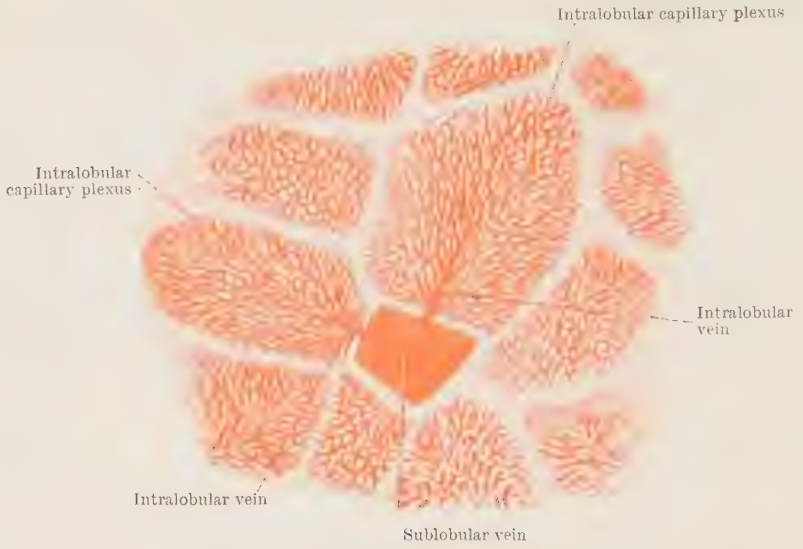

Fig. 790.—Liver of a Pig injected from the Hepatic Vein by T. A. Carter. (From a specimen left in the Anatomy Department of the Edinburgh University by Sir William Turner.)

central veins there is impaled, as it were, a **lobule** (which is more or less like a conical bullet in shape—Purser). These little conical lobules, with their intralobular or central veins running through them, are so numerous and so closely packed together, that they give rise to the practically solid liver tissue.

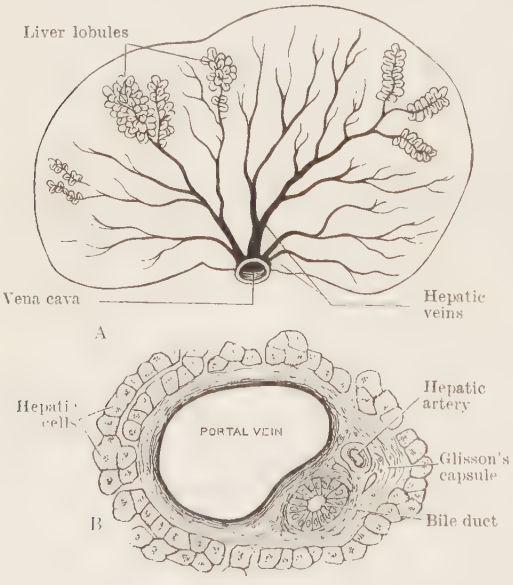

Fig. 791. Diagrams illustrating the Structure of Liver.

A, Arrangement of liver lobules around the sublobular branches of the hepatic vein; B, Section of a portal canal, showing its contained branches of the portal vein, hepatic artery, and bile-duct, surrounded by a prolongation of Glisson's capsule.

The lobules are surrounded by the interlobular branches of the portal vein, from which numerous twigs enter the lobule on all sides, and converging, join the central or intralobular vein (Fig. 792). This runs down through the centre of the lobule (Fig. 791, A), and opens at its base into a sublobular vein. The sublobular veins, uniting and growing larger by constant additions, finally form the hepatic veins, which open into the vena cava.

**Hepatic Cells.**—In the intervals between the branches of the capillaries, running from the interlobular to the intralobular veins (Fig. 792), are placed the polygonal-shaped, epithelial, hepatic cells. Between the cells run the **bile canaliculi** (ductus biliferi) which, passing out of the lobule (Fig. 792), join the **interlobular bile-ducts** (ductus interlobulares), and these uniting, finally end in the hepatic ducts.

## Development of the Liver.

In man, the liver first appears as two hollow outgrowths from the ventral wall of the foregut, in the position of the future duodenum. These outgrowths, which are formed entirely of endoderm (hypoblast), pass forwards and upwards into a mass of mesodermic tissue—called by His the **septum transversum**—which lies in front of the foregut just below the heart. In addition to constituting the mesodermic bed in which

the liver is developed, this mass also forms the chief rudiment of the future diaphragm; through it, too, pass the great fœtal veins on their way to the heart.

The two outgrowths give off numerous solid buds of endodermic cells—known as **hepatic cylinders**—which grow into the tissue of the septum transversum, and there branch and anastomose freely with one another, forming a complicated network, the

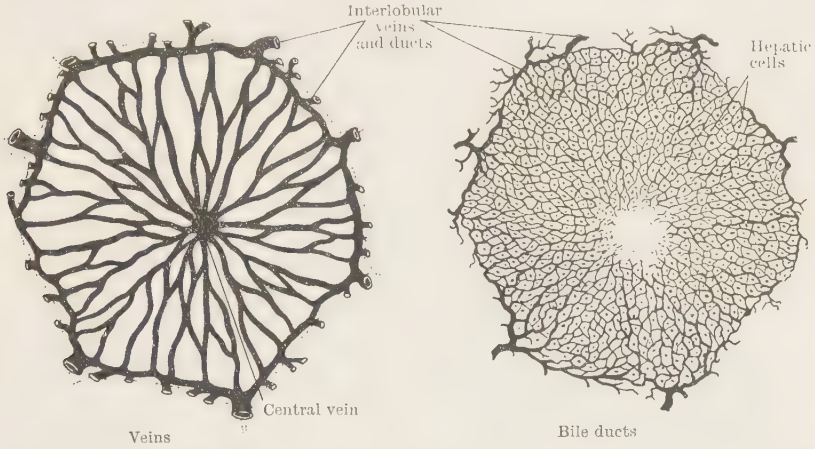

Fig. 792.—Diagram illustrating the arrangement of the blood-vessels (on left), and of the hepatic cells and bile ducts (on right) within a lobule of the liver. The first diagram shows the interlobular veins running around the outside of the lobule, and sending their capillaries into the lobule to join the central vein. In the second diagram the bile capillaries are seen, with the hepatic cells between them, radiating to the periphery of the lobule, where they join the interlobular bile-ducts.

meshes of which are occupied by blood-vessels. From the sides of these primary hepatic cylinders come off secondary cell-buds, which similarly branch and anastomose; and this process is continued until the mass of the liver is formed.

The two original outgrowths which open into the foregut close together, are soon succeeded by an evagination of the wall of the duodenum, which embraces the orifices of both, and subsequently forms the common bile duct; whilst the two primary diverticula, which are now connected with the evagination, form the right and left hepatic ducts.

The interlobular bile ducts and the bile capillaries are formed by a canalisation of the primitive hepatic cylinders which have been budded off from the original diverticula. And the gall-bladder is formed as an outgrowth from the common bile duct.

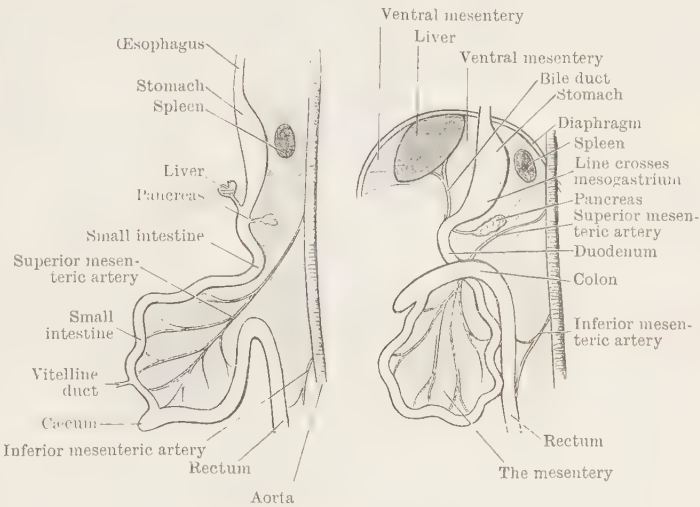

Fig. 793.—Two Diagrams to illustrate the Development of the Intestinal Canal.

The figure to the right shows the rotation of the intestinal loop round the superior mesenteric artery. In both figures the parts are supposed to be viewed from the left side.

As the liver increases in size, it begins to project down from the septum transversum into the abdominal cavity, so that now, instead of being situated within the septum, it looks like an appendage of its under surface. In other words, the septum begins to differentiate into two parts—a lower, the liver, and an upper, which constitutes the greater portion of the diaphragm, both of these having been at first one continuous mass. In the course

of development the separation of the two becomes more marked, and finally is complete everywhere except at the coronary and lateral ligaments behind, and at the falciform ligament in front, where they are still connected.

As the liver separates off from the future diaphragm, and descends into the abdomen, there descends with it the **ventral mesentery**—a fold which connects the stomach and duodenum with the anterior abdominal wall. This is divided by the liver into two parts—a posterior, stretching from the front (lesser curvature) of the stomach to the liver, which becomes the lesser omentum; and an anterior, stretching from the liver to the anterior wall of the abdomen, which forms the falciform ligament.

In early fœtal life the liver is relatively of enormous size. Up to the fourth or fifth month it almost completely fills the abdominal cavity, leaving but a small space below for the intestines. Subsequently its relative size is not so great; but even at birth it still occupies nearly half of the abdomen, and forms about $\frac{1}{18}$th of the body weight, whilst in the adult it is reduced to $\frac{1}{40}$th. At first the right and left lobes are nearly equal in size; subsequently, the right grows more rapidly than the left, so that at birth it is about twice, and in the adult four times, as large as the left. In the fœtus, and at birth, the caudate and Spigelian lobes are relatively larger than in the adult.

The changes which take place during development in the vessels connected with the liver are described on p. 934.

## THE PANCREAS.

The **pancreas** is an elongated glandular mass which lies transversely on the posterior abdominal wall, with its right end resting in the concavity of the duodenum (Fig. 794), and its left end touching the spleen. It secretes a digestive fluid—the pancreatic juice—which is conveyed to the duodenum by the *pancreatic duct*, and constitutes one of the chief agents in proteid digestion.

The absence of a true capsule, and the resulting distinct lobulation of the gland, give the pancreas a very characteristic appearance (Fig. 794).

**Position.**—The greater part of the gland lies in the epigastrium, but the tail and adjacent part of the body extend into the left hypochondrium.

The head is placed opposite the second and upper part of the third lumbar vertebra, whilst the body runs to the left, about the level of the first lumbar vertebra. It should be added, that very often the lower portion of the head projects some distance below the subcostal plane, and thus lies in the umbilical region.

In **shape** the pancreas, when hardened *in situ*, is very irregular (Fig. 794), its right end being flattened and hook-like, whilst the rest of the organ is prismatic and three-sided. It may, perhaps, in general form be best compared to the letter J placed thus ⊂, particularly if the stem and hook of the letter be thickened.

The gland is divisible into a head, a neck, and a body. The **head** corresponds to the hook of the ⊂, and runs downwards and to the left along the second and third portions of the duodenum. The stem of the ⊂ represents the **body** of the gland, and the narrow part connecting the two is the **neck** (Symington).

When removed from the body without previous hardening, the pancreas loses its true form, and becomes drawn out into a slender, elongated, tongue-shaped mass, with a wider end turned towards the duodenum, and a narrow end corresponding to the tail.

Its total *length*, when fixed *in situ*, is about 5 or 6 inches (12·5 to 15 cm.); after removal, if not previously hardened, it is easily extended to a length of 8 inches (20 cm.).

Its *weight* is usually about 3 ounces (87 grammes).

**Relations.**—The general position and relations of the pancreas may be briefly expressed as follows:—The head (Fig. 794) lies in the concavity of the duodenum, with the vena cava and aorta behind it; the body crosses the left kidney and suprarenal capsule; and the tail touches the lower part of the spleen. The greater part of the organ lies behind the stomach, which must be detached from the great omentum, and turned upwards, in order to expose it.

In describing the detailed relations, each part of the organ will require to be considered separately.

The **head** (caput pancreatis) is the large flattened and somewhat disc-shaped portion of the gland which lies in the concavity of the duodenum, extending along its second and third portions almost as far as the duodenal-jejunal flexure. *Above*, in its right half, it is continuous with the neck; whilst to the left of this it is separated from the neck by a deep notch (incisura pancreatis), in which lie the superior mesenteric vessels (Fig. 794).

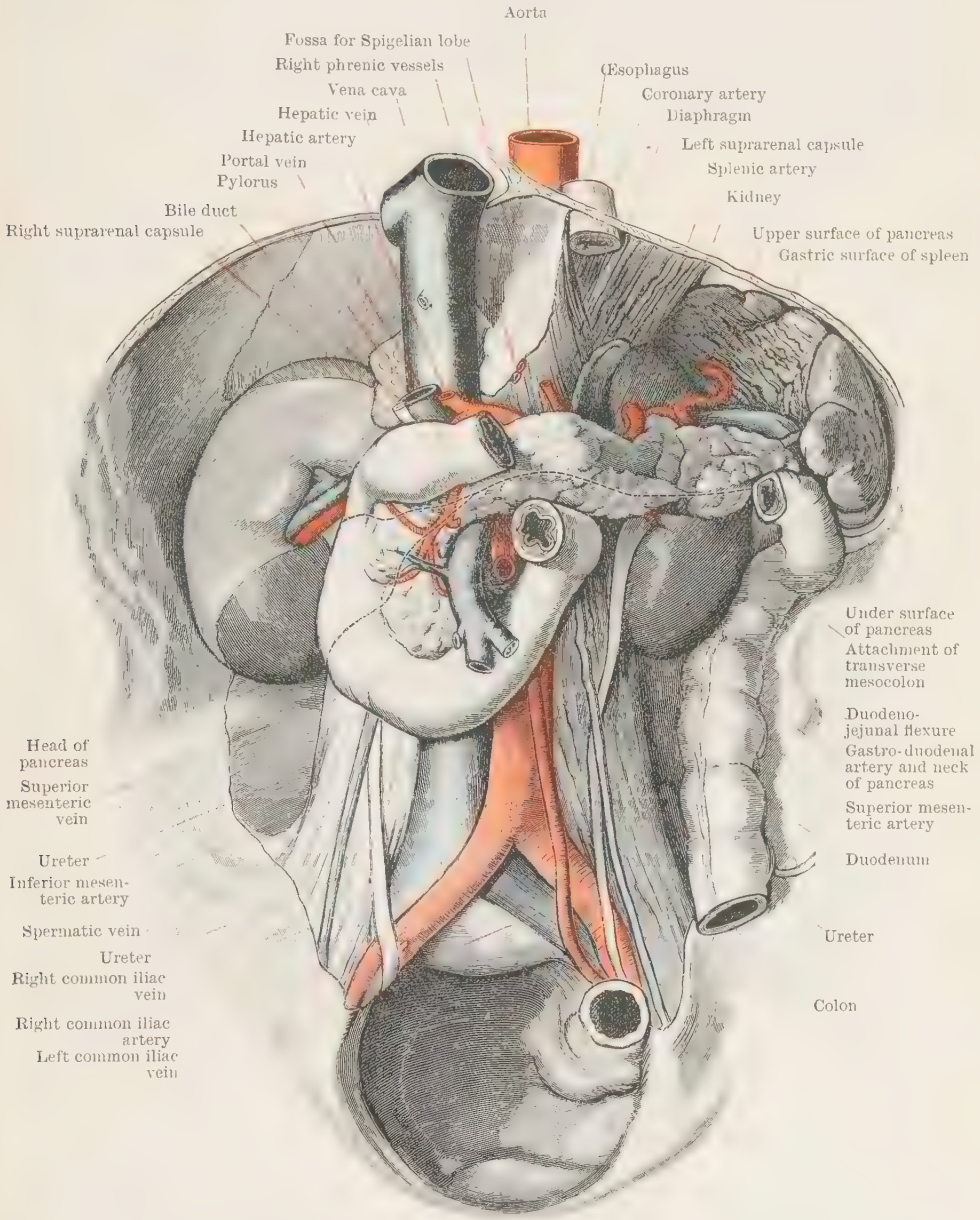

FIG. 794.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and the fossa for the Spigelian lobe. In taking out the liver, the vena cava was left behind. The stomach-bed is well shown. (From a body hardened by chromic-acid injections.)

Its *right* and *lower borders* are moulded on to the side of the duodenum, which lies in a groove of the gland substance—the common bile duct being interposed as far down as the middle of the second portion of the duodenum. The *posterior surface* of the head is applied to the front of the inferior vena cava; it also lies on the renal vessels, and, at its left end, on the aorta as well. Its *anterior surface* is in contact above and on the right with the beginning of the transverse colon (Fig. 795), without the inter-

position of the peritoneum as a rule. Below this it is clothed by peritoneum, and is covered by the small intestine.

The **superior mesenteric vessels**, after passing forward through the pancreatic notch, descend in front of that portion of the head (processus uncinatus) which runs to the left along the third part of the duodenum. The **superior pancreatico-duodenal vessels** run downwards, and break up on the front of the head (Fig. 794).

The **neck** (Fig. 794) is a comparatively attenuated portion of the gland which lies in front of the portal vein, and connects the head to the body. Springing from the upper and right portion of the head, it runs upwards and to the left for about 1 inch (25 mm.), and then passes into the body.

The neck is about $\frac{3}{4}$ inch (18 mm.) in width, and less than $\frac{1}{2}$ inch (12·5 mm.) in thickness. *In*

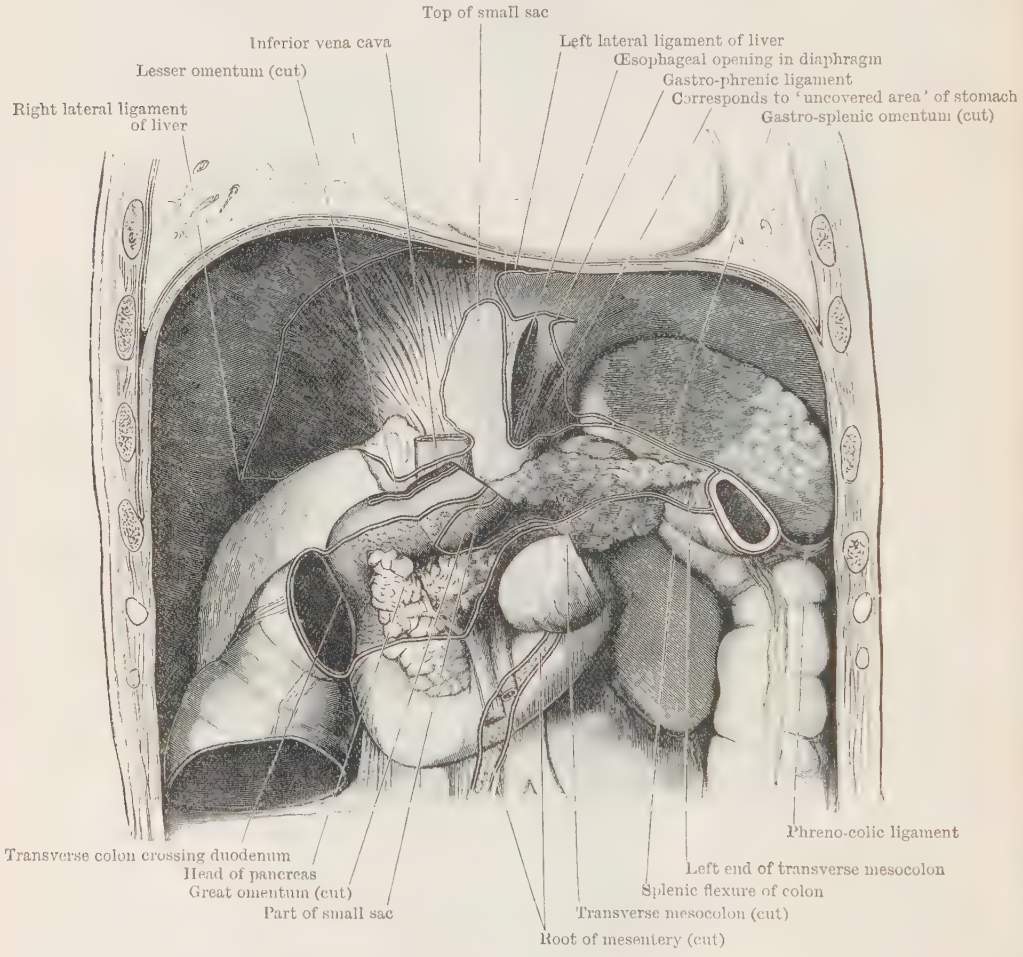

FIG. 795.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

*front and to its right* lie the first part of the duodenum and the pylorus; *behind and to the left* it rests upon the beginning of the portal vein, which is formed under cover of its lower border, by the union of the splenic and superior mesenteric veins. It has a partial covering of peritoneum on its anterior surface; and its beginning is generally marked off from the head by the gastro-duodenal artery, with its continuation the superior pancreatico-duodenal, which lies in a groove of the gland substance between the head and neck.

The **body** is of a prismatic form, largest where it lies in front of the left kidney, and usually somewhat tapering towards the tail (Fig. 795). Beginning at the termination of the neck, it runs backwards and to the left across the front of the left kidney, beyond which its extremity or tail comes in contact with the spleen. When hardened *in situ* it presents three surfaces—superior, inferior, and posterior—all of which are of nearly equal width (namely, about $1\frac{1}{4}$ inch: 31 mm.).

The **upper surface** (facies anterior) is widest towards the left end; it looks upwards and forwards (Fig. 794), and forms a considerable portion of the stomach-bed. This surface is completely covered by peritoneum, derived from the posterior wall of the small sac, which latter separates the pancreas from the under surface of the stomach. Towards its right extremity it presents an elevation or prominence where the body joins the neck. This projects against the back of the small omentum when the stomach is distended, and is consequently known as the **omental tuberosity** (tuber omentale).

The **inferior surface of the body**, which, like the superior, is, as a rule, widest towards its left end, looks downwards and slightly forwards. It is completely covered by peritoneum, viz. the descending layer, derived from the transverse mesocolon (Fig. 795). It lies in contact with the duodeno-jejunal flexure towards its right end, with the splenic flexure of the colon near its left end, and with a mass of small intestine (jejunum, which is always found packed in beneath it) in the rest of its extent.

The **posterior surface of the body** looks directly backwards, and is entirely destitute of peritoneum. It is connected by areolar tissue to the posterior abdominal wall with the organs lying upon it. From right to left these are: the aorta with the origin of the superior mesenteric artery, the left renal vessels, the left suprarenal capsule, and the left kidney. In addition, the splenic artery runs its tortuous course to the left behind the upper border of the pancreas, whilst the splenic vein runs, behind the gland, at a lower level than the artery.

The three surfaces of the body of the pancreas are separated by three borders. The **anterior border** is the most prominent, and gives attachment to the transverse mesocolon (Fig. 795). It is, as it were, squeezed forward, by the pressure of the stomach above and the small intestine below, into the interval between these two sets of viscera, thus following the line of least resistance (Cunningham). Towards the neck this border is no longer prominent, but becomes rounded off, so that here the upper and lower surfaces are confluent.

The cœliac axis projects over the **upper border**, and sends its hepatic branch to the right, resting upon it, whilst the splenic artery runs to the left behind it (Fig. 794). The **inferior border** calls for no special description.

The **tail of the pancreas** is the somewhat pointed left end of the body, which is in contact with the lower portion of the gastric surface of the spleen. It usually presents an abrupt, blunt ending, in which case it is related to the spleen in the manner just described; or it may be elongated and narrow, when it bends backwards around the outer aspect of the kidney, and beneath the base of the spleen. In either case it lies in contact below with the splenic flexure of the colon (Fig. 794).

**Peritoneal Relations of the Pancreas.**—The posterior surface of the pancreas is entirely free from peritoneum. The other surfaces derive their peritoneal covering from the prolongation of the two layers of the transverse mesocolon, which latter is attached to the anterior border of the gland, from the tail to the neck. At this border the two layers separate (Fig. 777, p. 1098), the anterior—derived from the small sac—passing backwards and upwards over the superior surface; the posterior—derived from the large sac—turning downwards and backwards along the inferior surface.

As the transverse mesocolon is followed to the right it ceases, as a rule, that is, its two layers fail to meet about the neck of the pancreas (Fig. 795). Beyond this the posterior surface of the colon is generally free from peritoneum, and is connected by areolar tissue to the front of the head of the gland. Below the level of the colon the head is covered by the continuation downwards of the peritoneum from the under surface of that gut. Often, however, the transverse mesocolon is continued to the right as far as the hepatic flexure, when the anterior surface of the head is then completely covered by peritoneum.

**Ducts of the Pancreas.**—Almost invariably two ducts are found in the interior of the pancreas—the **pancreatic duct** proper and the **accessory pancreatic duct.**

The **pancreatic duct** (ductus pancreaticus Wirsungi) begins near the tip of the tail by the union of small ducts from the lobules forming that part of the organ. From this it pursues a rather sinuous or zigzag course (Fig. 796) through the axis of the gland, at first running transversely to the right, until the neck is reached, then bending downwards towards the head. Here it approaches the second portion of the duodenum, and meeting the bile duct, the two pierce the inner wall of the gut obliquely (for $\frac{1}{2}$ to $\frac{3}{4}$ of an inch, 12 to 18 mm.), and open, by a common orifice on the bile papilla, about $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.) beyond the pylorus (see p. 1120).

In its course through the gland the duct receives numerous branches, which join it, as a rule, at very open angles. These, as well as the main duct itself, are easily recognised by the whiteness of their walls, as contrasted with the darker colour of the gland tissue. The main duct receives branches from all portions of the pancreas, and towards its termination has attained a considerable size (namely, $\frac{1}{10}$th to $\frac{1}{6}$th of an inch—2·5 to 4 mm.—when fattened out, or somewhat larger than a crow quill).

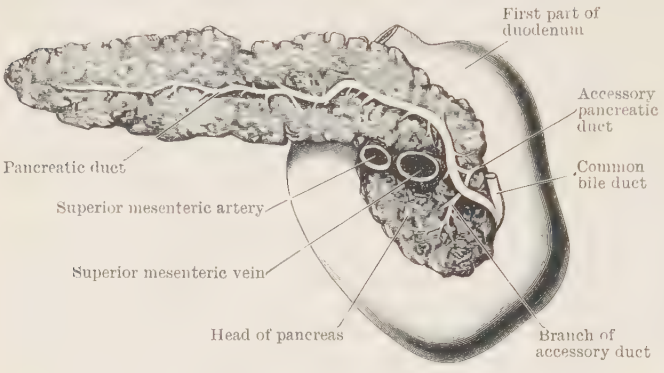

FIG. 796.—THE PANCREAS AND DUODENUM FROM BEHIND, with the pancreatic duct exposed.

The superior mesenteric vessels are also shown in section, passing forward, surrounded by the recurved portion of the head of the pancreas.

The **accessory pancreatic duct** (ductus pancreaticus accessorius, Santorini) is a small and variably-developed duct (Fig. 796) which opens into the duodenum about $\frac{3}{4}$ of an inch above and somewhat in front of (*i.e.* ventral to) the pancreatic duct. From the duodenum it runs to the left and downwards, and soon divides into two or more branches, one of which joins the pancreatic duct, the others pass down and receive the ducts from the lower part of the head. It is generally supposed that the current flows from this into the main duct, and not into the duodenum, as a rule, except in early life.

**Physical Characters and Structure of the Pancreas.**—The pancreas is of a reddish cream colour, soft to the touch, and distinctly lobulated. The lobules are but loosely held together by their small ducts and by loose areolar tissue; for, as already pointed out, the pancreas is devoid of a regular capsule, and possesses instead merely an adventitious coat of fine connective tissue.

The gland belongs to the class of acino-tubular glands, its alveoli or acini being elongated like those of Brunner's glands; otherwise it corresponds very closely to a serous salivary gland, the general structure of which will be found on p. 1007.

**Variations.**—The chief variations found are:—(1) A separation of the part of the head, known as the uncinate process, which then forms a *lesser pancreas*. (2) A growth of the pancreas around the duodenum, which it may practically encircle for a short part of its course. And (3) an opening of its duct into the duodenum, independently of the bile duct. An *accessory pancreas* (pancreas accessorium) is also sometimes found in the wall of the stomach or of the jejunum. Diverticula of the duodenum, already described (p. 1070), ought perhaps to be mentioned in this connexion.

**Vessels.**—The **arteries** of the pancreas are:—(1) The **superior pancreatico-duodenal**, a branch of the gastro-duodenal artery, which runs down on the front of the head (Fig. 794), sending branches outwards to the duodenum, as well as numerous twigs into the substance of the pancreas. (2) The **inferior pancreatico-duodenal**, a branch of the upper part of the superior mesenteric artery; it runs upwards and to the right across the back of the head, and sends branches to it and to the duodenum, one of which runs between the head and the duodenum. These two pancreatico-duodenal arteries anastomose around the inferior border of the head. (3) The **inferior pancreatic branch** of the superior mesenteric (or sometimes of the gastro-duodenal) artery, a considerable branch, which arises along with, or near, the last, and runs to the left along the lower border of the pancreas, often even as far as its tail. (4) **Pancreatic branches** of the **splenic artery**, are several (3 to 5) fair-sized branches which come off from the splenic as it runs behind the upper border of the gland; they enter the pancreas immediately, and traverse its substance from above downwards, some sending branches in both directions along the course of the pancreatic duct. (5) Small **pancreatic branches** also arise from the **hepatic artery** whilst it rests on the upper part of the gland, and enter it immediately. The **pancreatica magna**, which is described as accompanying the duct from left to right, does not seem to exist in the majority of cases.

The **veins** are: (1) An *anterior pancreatico-duodenal* (Fig. 794), which passes downwards and to the left, on the front of the head, and joins the superior mesenteric; (2) a *posterior pancreatico-duodenal*, which crosses the back of the head, and opens into the portal vein; (3) several small pancreatic veins which join the splenic; and (4) some from the upper part of the head and

neck join the portal, which latter vein ultimately receives all the blood returned from the gland.

The **lymphatics** pass chiefly with the splenic lymphatics to the cœliac glands; some also are connected with a few glands which lie near the upper end of the superior mesenteric vessels. All the lymphatics of the organ pass ultimately to the cœliac glands.

The **nerves**, which are almost entirely non-medullated, come from the solar plexus, through the cœliac, splenic, and superior mesenteric plexuses.

## Development of the Pancreas.

The pancreas is developed at a very early period in man (being visible in embryos of 8 mm.) from at least two independent hollow outgrowths, one of which takes place from the ventral aspect of the future duodenum in connexion with the diverticula which form the liver; the other from the dorsal side of the tube. From this latter, which springs from the duodenum nearer to the pylorus than the ventral outgrowth, the greater part of the gland is formed, whilst the ventral diverticulum gives rise to the smaller portion. About the sixth week the two outgrowths meet, and they, as well as their ducts, fuse. At first the main duct of the gland is connected with the dorsal outgrowth; later on, the portion of this duct between the duodenum and the meeting of the two ducts lags behind in its growth, whilst the corresponding portion of the ventral duct increases rapidly in size; and finally, this latter appears to be the direct continuation of the main duct, whilst the former, and now much smaller, dorsal duct becomes the accessory pancreatic duct. The two ducts come to open on the inner or left side of the gut, owing to the turning over of the duodenum on its right side, and the unequal growth of different portions of its wall.

The primary diverticula give off hollow lateral buds, which in their turn give off others, and this process is continued until the mass of the gland is formed. The terminal buds thus produced develop into the gland acini, whilst the others form the gland ducts.

When first formed in the embryo, the pancreas runs upwards towards the head, behind the stomach and between the two layers of the mesogastrium, so that it possesses a complete peritoneal covering. Subsequently, as a result of the changes which take place in the position of the stomach, it turns over on to its right side, and becomes adherent to the posterior abdominal wall, its head occupying the concavity of the duodenum, and its tail passing towards the spleen. The peritoneum of its posterior surface is soon lost by absorption; but it persists on its anterior aspect.

# THE URINOGENITAL SYSTEM

By A. Francis Dixon.

## THE URINARY ORGANS.

The **kidneys**, or glands which secrete the urine, are a pair of almost symmetrically-placed organs, situated in the posterior part of the abdominal cavity, one on each side of the lower movable portion of the vertebral column. The fluid secreted by the kidneys is received into the upper expanded portions of a pair of long tubes, the **ureters**, by them is conducted to the **bladder**, which is placed within the pelvic cavity. From the bladder the urine is passed, during micturition, along the **urethra** to the exterior. In the male the urethra is a relatively long passage, and traverses the prostate gland and the whole length of the penis; in the female it is a short tube, and opens on the surface just above the vaginal orifice.

### THE KIDNEYS.

The **kidney**, when removed from a fresh subject, presents a bean-shaped contour. It is of a dark brown-red colour, and is surrounded by a thin glistening **capsule** (tunica fibrosa), which gives to the whole organ a uniformly smooth surface. The kidney is not a solid body, but contains a cavity called the **renal sinus**, the opening into which, termed the **hilum** (hilum renalis), is situated on the inner and anterior part of the organ. Each kidney measures about $4\frac{1}{2}$ inches in length, 2 inches in width, and about $1\frac{1}{4}$ inch in thickness, and is placed so that its long axis is nearly vertical. The weight of the adult kidney is about $4\frac{1}{2}$ ounces. In the freshly-removed kidney the upper and lower ends are smoothly rounded, and the *upper end* (extremitas superior) is usually a little more bulky than the *lower* (extremitas inferior). The *outer border* (margo lateralis), which is opposite to the hilum, is rounded and convex, while the *inner border* (margo medialis), on which the hilum is placed, is concave from above downwards. These two borders separate the *anterior surface* (facies anterior) from the *posterior surface* (facies posterior) of the kidney.

The capsule, which envelops the whole organ, divides in the region of the hilum into two layers, one of which is continued over the lips of the hilum into the interior of the kidney, and lines the walls of the kidney sinus. The other layer is prolonged to form a tubular sheath for the vessels and nerves of the kidney before they pass through the hilum to enter the sinus, within which they break up into branches. These branches, piercing the wall of the sinus, enter the substance of the kidney. The upper expanded portion of the ureter leaves the sinus through the hilum in company with the blood-vessels and nerves.

**Position of the Kidneys.**—The precise level of the kidney in the abdominal cavity is subject to a considerable amount of variation, and also it is usual to find a difference in the levels of the right and left kidneys of the same individual. Most frequently the left kidney is on a higher level than the right, but in many cases the kidneys occupy the same level, or, the more usual condition being reversed, the right kidney is a little higher than the left.

If a line be drawn round the body at the level of the lowest part of the thoracic wall, the whole, or almost the whole, of the left kidney will be found to lie above the level of the plane (subcostal) so determined. It is, therefore, situated in the subcostal zone of the abdominal cavity. The right kidney, however, although it lies for the most part in the subcostal zone, usually projects at its lowest part slightly below the subcostal plane, and hence lies to a small extent in the umbilical zone. It is often stated that the kidneys are placed on a somewhat lower level in the female than in the male.

By far the greater part, usually two-thirds or more, of the kidney lies to

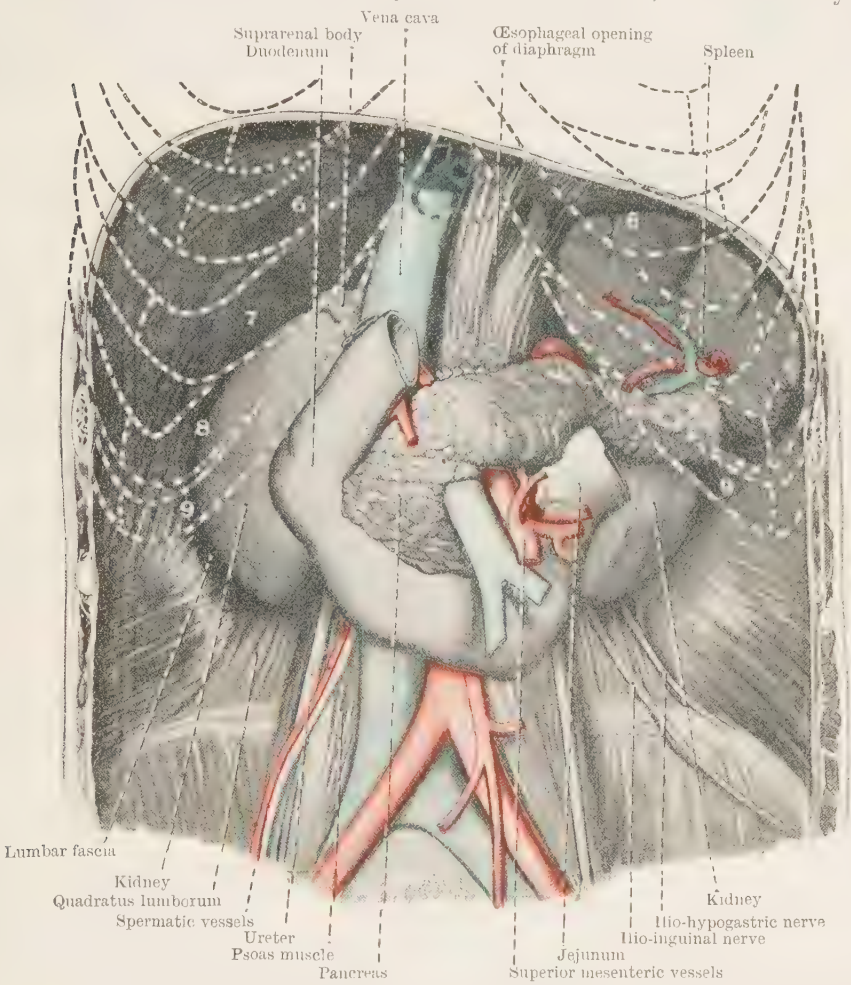

Fig. 727.—Dissection to show the Position and Relationships of the Kidneys. The outlines of the costal arches are indicated, and it will be noted that in the subject from which the drawing was made the lower ends of both kidneys lay below the level of the subcostal zone.

the inner side of a line drawn vertically upwards through the middle point of Poupart's ligament.

The posterior aspect of the kidney is closely applied against the muscles attached to the bodies of the last dorsal and upper three lumbar vertebræ, and is placed in front of the last rib and of the transverse processes of the upper three lumbar vertebræ. In some cases, more frequently on the left side of the body, the eleventh rib also lies behind the upper part of the kidney. The relationship of the kidney to the lower two ribs is, however, very inconstant, owing partly to the great variability in size and inclination of these bones (Fig. 779).

The lower end of the kidney is usually situated from 1¼ to 2 inches above the highest part of the crest of the ilium; the interval between the kidney and the ilium being usually greater on the left side of the body.

Sometimes the lower end of the kidney lies on the same level as, or only a short distance above, the iliac crest, and this may be due to the crest rising to a higher level than usual, the kidney occupying its normal position in relation to the vertebral column. It is important to remember that normally the kidney moves upwards and downwards during life, following the respiratory movements of the part of the diaphragm against which it rests.

The kidneys are placed behind the peritoneum, and project into the posterior part of the abdominal cavity. Each is surrounded by a considerable amount of loose tissue, often loaded with fat, the fatty tissue (capsula adiposa) being present in greater quantity round the margins of the organ, and only to a less extent in front of and behind the kidney. In this fat the renal vessels and nerves lie before they enter the organ, and the adipose tissue is continued, along with the vessels,

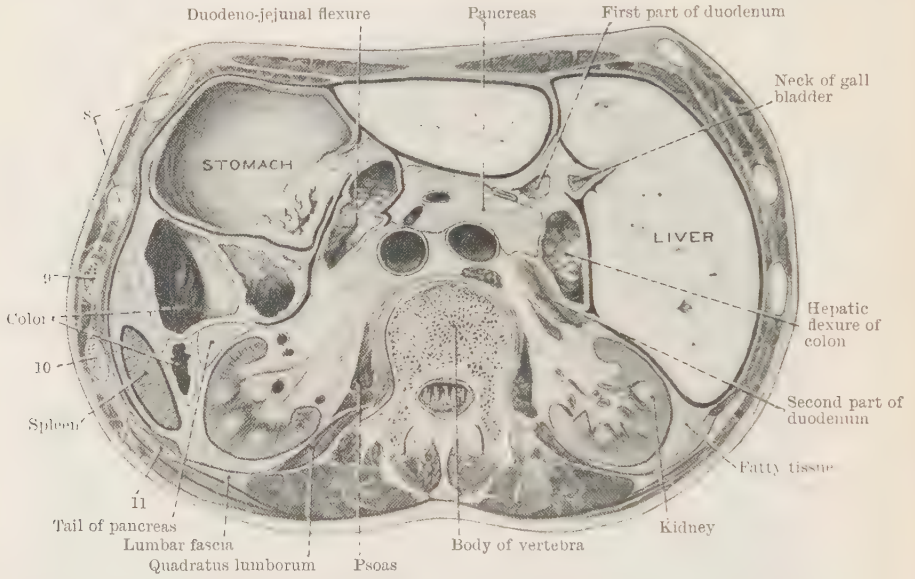

FIG. 798.—TRANSVERSE SECTION THROUGH THE ABDOMEN AT THE LEVEL OF THE SECOND LUMBAR VERTEBRA. The plane of the section is somewhat oblique, being lower behind than in front. The costal arches are numbered 8-11. On the right side the posterior layer of the renal fascia is indicated. (From a specimen in the Anatomical Department, University College, Cardiff.)

through the hilum into the kidney sinus, where it fills up all the space unoccupied by the vessels and nerves.

The long axis of each kidney is somewhat oblique, as the upper end of the organ approaches nearer to the middle line than the lower. The surface of the kidney, which is applied against the muscles forming the posterior wall of the abdomen, looks, as a whole, backwards and inwards, and that which projects into the abdominal cavity forwards and outwards. Hence it happens that the outer border of the kidney lies on a posterior plane to the inner border. The kidney is rotated in this manner on its long axis to such a degree that the inner margin and hilum are scarcely visible from behind, and but a limited view of the outer border can be obtained in front (Figs. 800 and 803).

Embedded in the soft fatty tissue surrounding the kidney is a layer of fibrous tissue to which the term **fascia renalis** is applied. This fascia surrounds the kidney and a considerable amount of its fatty capsule in the form of a loose sheath, in which may be distinguished anterior and posterior walls. The sheath is open below and internally, but closed above and to the outer side of the kidney by the apposition of its walls. Externally the anterior and posterior walls of the sheath come into contact and are connected with the retro-peritoneal tissue; internally the layers forming these walls remain distinct and the anterior one is continued across the middle line, in front of the renal vessels and the aorta, to join the corresponding layer of the opposite side, while the posterior wall fuses

with the fascia covering the psoas and quadratus lumborum muscles. Inferiorly, below the level of the kidney, the anterior and posterior layers of the renal fascia remain distinct and can be traced downwards into the iliac fossa. Above the level of the kidney and the suprarenal body the layers of the renal fascia unite and join the fascia covering the diaphragm. It has been suggested that the terms "tunica adiposa" and "peri-renal fat" should be restricted to the loose fatty tissue enclosed along with the kidney within the sheath of renal fascia, and that the term "para-renal body," or fat, be applied to the tissue outside the sheath. The fibrous capsule of the kidney is joined to the loose sheath formed by the renal fascia by numerous connective tissue strands, which traverse the peri-renal fat and undoubtedly assist in fixing the kidney. The para-renal fat is present in greatest

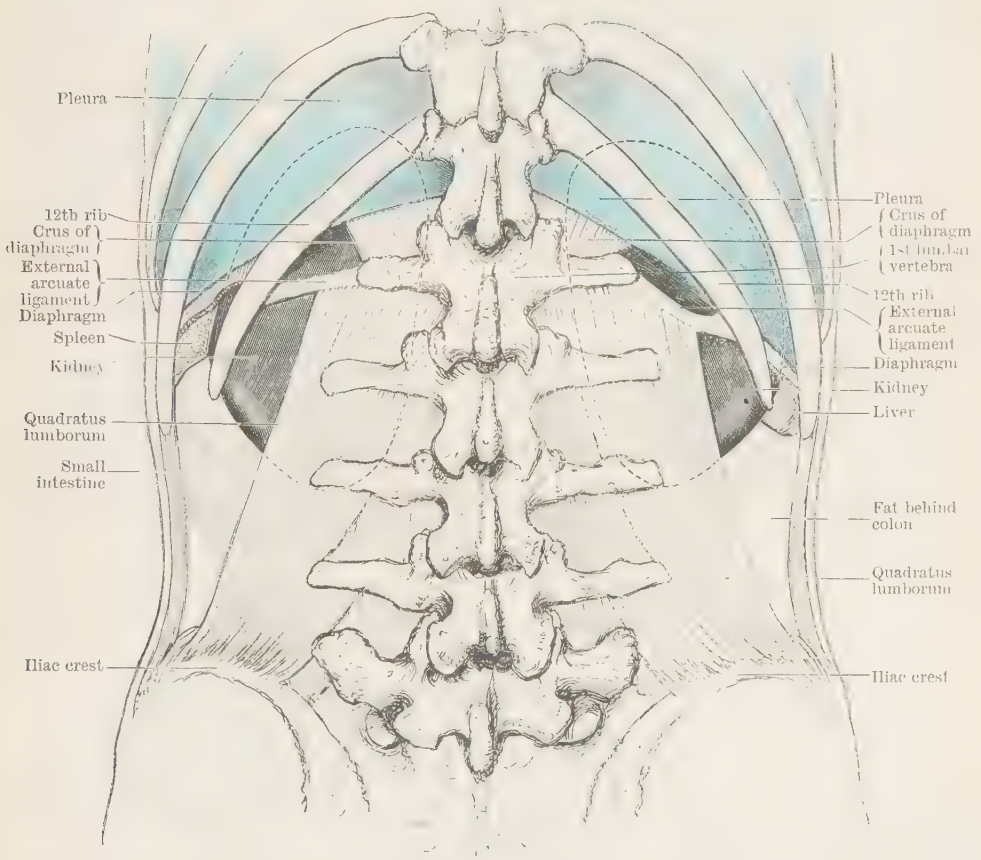

FIG. 799.—THE POSTERIOR RELATIONSHIPS OF THE KIDNEYS. The dotted lines indicate the contours of the kidneys. The drawing is made from a model prepared by Professor Cunningham.

quantity behind the lower part of the kidney, and in this position the layer of fibrous tissue, separating the two masses of fat and forming the posterior layer of the sheath of renal fascia, is usually well marked.

**Fixation of the Kidney.**—The kidney is not held in its place by any distinct ligaments, or special folds of peritoneum, but its fixation depends, to a large extent, on the pressure and counter-pressure which is exerted upon it by neighbouring structures, and on its connexions with the **renal fascia** above described.

**Posterior Relations and the Posterior Surface of the Kidney.**—The muscles of the posterior abdominal wall on which the kidney rests are the psoas, the quadratus lumborum, the diaphragm, and the tendon of the transversalis abdominis. The abdominal surfaces of these muscles do not lie on the same plane, but slope towards one another, and thus the bed on which the kidney rests is not flat. The posterior aspect of the kidney, when *in situ*, adapts itself to the inequalities of the

surface against which it is placed, and so we find on a kidney which has been carefully fixed and hardened before it has been disturbed, areas marked off for the different planes of these muscles. When the kidney is in position, slight ridges or elevations separating these areas correspond to the angles along which the different muscular planes meet. These ridges can be observed in the hardened kidney after its removal from the body, but usually they are not very sharply defined, the angles between the muscular planes being very obtuse.

A kidney removed from the body after having been hardened *in situ* (Fig. 800) presents an area near the inner part of its posterior surface adapted to the anterior aspect of the psoas muscle. This part of the posterior surface looks inwards and slightly backwards. Farther out there is a larger area which rests against the quadratus lumborum and looks more directly backwards. These two areas are separated by a rounded ridge which fits into the angle between the muscles men-

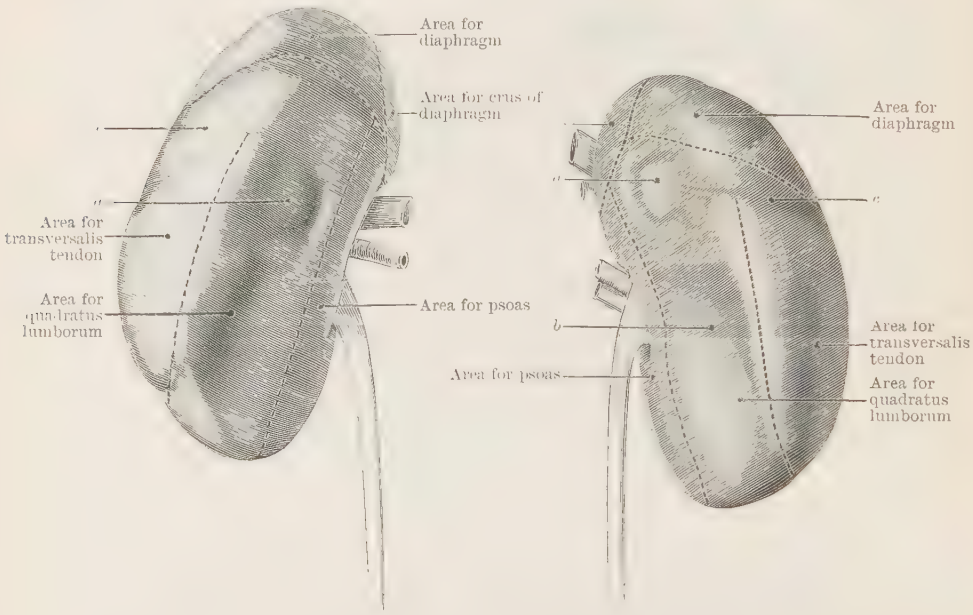

FIG. 800.—THE KIDNEYS VIEWED FROM BEHIND. Same specimen as Fig. 803. The dotted lines mark out the areas in contact with the various muscles forming the posterior abdominal wall.

*a*. Depression corresponding to the transverse process of the first lumbar vertebra.
*b*. Depression corresponding to the transverse process of the second lumbar vertebra.
*c*. Depression corresponding to the twelfth rib.

tioned. Beyond the area in contact with the quadratus lumborum is the thick outer border of the kidney.

Towards the upper end of the kidney the posterior surface slopes forwards and rests upon the diaphragm. Indeed the upper part of the kidney is, as a whole, bent slightly forwards, following that part of the arch of the diaphragm on which it rests, and thus a narrow interval is left, in which the pleural cavity passes down behind the upper end of the kidney (Fig. 799). This relationship of the pleural cavity to the kidney is of importance in connexion with surgical operations on the organ, performed through a lumbar incision. The portions of the diaphragm to which the kidney is applied are the crus and the parts arising from the last rib and arcuate ligaments.

In addition to these surfaces, or facets, for the muscles with which it is in contact, the posterior aspect or outer border of the kidney often shows a groove for the last rib, another for the external arcuate ligament, and two or three depressions for the tips of the transverse processes of the upper two or three lumbar vertebræ. In some cases also faint narrow grooves are to be seen for the nerves which pass downwards and outwards between the kidney and quadratus lumborum—namely, the last dorsal nerve and the ilio-hypogastric and ilio-inguinal nerves.

It is probable that some at least of the depressions on the posterior aspect of the kidney are produced after death, and are caused by the weight of the other abdominal organs pressing the

kidney backwards against the more resisting structures of the abdominal wall, at a time when the muscles behind the kidney have become flaccid. When much fat is present the posterior aspect of the kidney is more uniformly convex.

The **outer border** in its middle and lower part is rather a surface than a border, and looks for the most part directly backwards. It rests on the anterior surface of the lumbar fascia, and lies to the outer side of the quadratus lumborum. The outer border is narrowest above, and widest just below its middle point, corresponding to the greater thickness of this part of the kidney.

In many ways it would be more satisfactory to apply the term **muscular surface** (facies muscularis) collectively to the areas described here as posterior surface and outer border, and in like manner the term **visceral surface** (facies visceralis) might be suitably applied to the so-called anterior surface of the organ. The edge separating the visceral from the muscular surface is the actual outer border of the kidney.

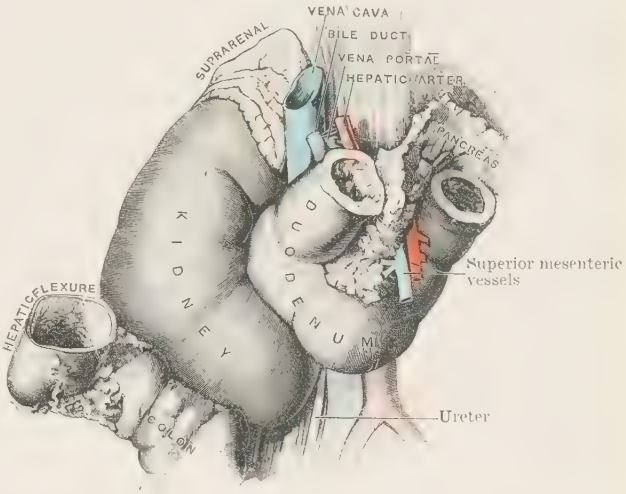

FIG. 801.—RIGHT KIDNEY AND DUODENUM. (D. J. Cunningham.)

**Anterior Relations and the Anterior Surface of the Kidney.**—The anterior relations of the kidneys not only differ on the two sides of the body, but also many of the structures related to the anterior surface of each kidney undergo frequent changes in position during life.

A small area on the upper part of the anterior surface of the **right kidney** is in relation to the corresponding suprarenal capsule (Fig. 803). The rest of the upper part of the anterior surface is in contact with the visceral surface of the liver, which is often hollowed out to form a fossa for the kidney. The suprarenal capsule is bound to the kidney by connective tissue, while the part of the kidney in relation to the liver is, like the liver itself, covered by peritoneum, and thus the two organs, although closely applied, are really separated by a part of the general peritoneal cavity. In front of the lower end of the right kidney are usually found two parts of the alimentary canal—namely, the descending part of the duodenum and the hepatic flexure, or the commencement of the transverse colon. The part of the kidney related to the duodenum lies to the inner side of the area which touches the colon, but the exact amount of the kidney in contact with each of these two parts of

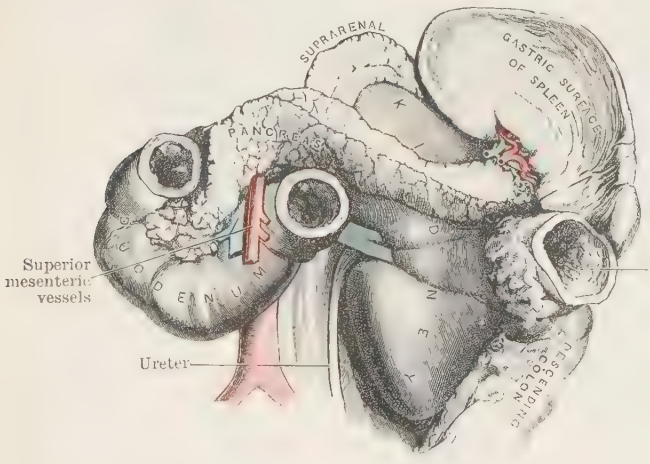

FIG. 802.—LEFT KIDNEY, THE PANCREAS, THE SPLEEN, AND THE DESCENDING COLON. (D. J. Cunningham.)

intestine varies much in different subjects. Frequently the colon and the kidney are both covered by peritoneum where they are in contact, but the duodenum is bound down to the kidney by the peritoneum. In addition to the structures mentioned, some portion of the ileum, or of the jejunum, is often found in contact with a small part of the right kidney.

In some cases the peritoneal cavity does not pass upwards in front of the upper end of the right kidney, and thus the anterior aspect of this part of the organ is, like the suprarenal body, bound by connective tissue to the uncovered area of the liver.

In front of the extreme upper and inner part of the **left kidney** is the inferior portion of the left suprarenal capsule; at a lower level the upper part of the left kidney is in contact with the stomach and pancreas. The suprarenal capsule and the pancreas are bound down to the kidney by connective tissue, but the stomach is separated from the part of the kidney with which it is in apposition, by the lesser sac of the peritoneum. The part of the kidney in actual contact with the stomach is usually a small, somewhat triangular, area situated above the level at which the pancreas crosses the organ. The renal surface of the spleen is related to the anterior surface of the left kidney in its upper and outer part, the two organs being separated by a portion of the general peritoneal cavity, except along the area where spleen and kidney are connected by the lieno-renal ligament. The anterior surface of the lower end of the left kidney is related, towards the inner side, to a part of the jejunum, and towards the outer side to a part of the splenic flexure of the colon.

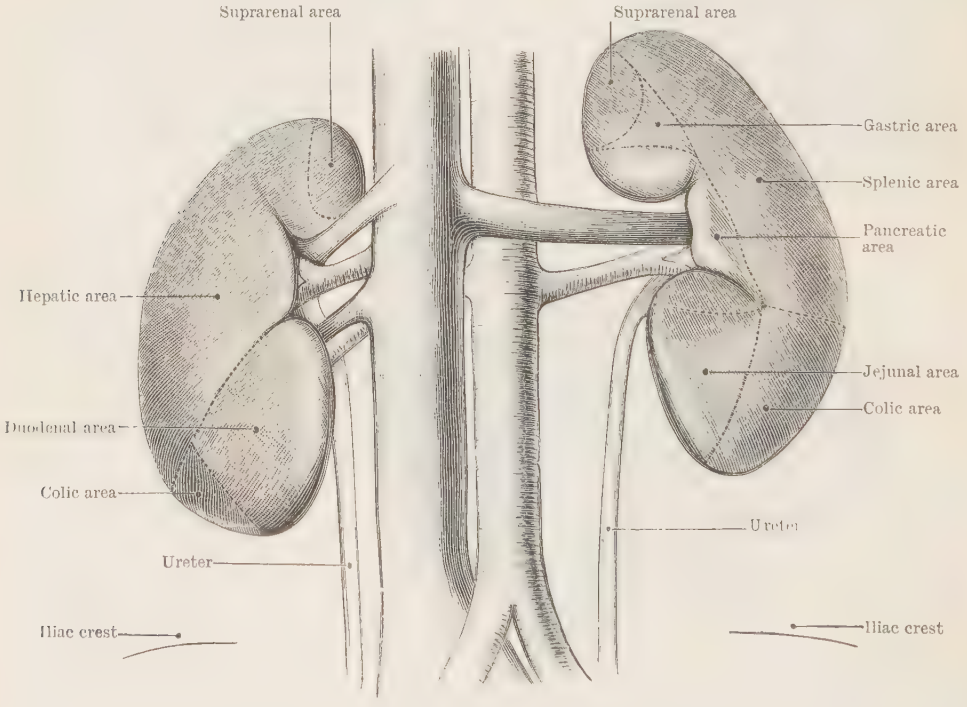

FIG. 803.—THE KIDNEYS AND GREAT VESSELS, viewed from the front. The drawing was made, before removal of the organs, from a specimen in which the viscera had been hardened *in situ*. The dotted lines mark out the areas which were in contact with the various other abdominal viscera.

The right and left colic arteries, or their branches, as they pass outwards to reach the colon, are often related to the anterior aspects of the corresponding kidneys. The splenic vessels pass outwards in front of the inner part of the left kidney (Fig. 797).

The anterior surface of a kidney, which has been hardened *in situ*, is, like the posterior surface, not uniformly rounded, but marked by a series of impressions corresponding to the different structures which lie in contact with it. In the case of each kidney, the most prominent region on the anterior surface lies below the

level of the middle of the kidney, and corresponds to the thickest part of the organ. From this prominence on the anterior surface a series of more or less flattened planes slope away towards the borders of the kidney. These flattened areas are the impressions formed by the viscera which lie in front of the kidney.

In the case of the *right kidney*, three impressions can usually be distinguished on the anterior surface. One occupies the whole of the upper part of the organ, and is the **hepatic impression** (impressio hepatica); another stretches from the most prominent point to the lower end of the kidney, and is related to the colon; while the third extends along the inner margin, below the hilum, and is in contact with the second part of the duodenum (Fig. 803). The relative sizes of these three impressions vary much in different specimens.

On the *left kidney*, also, three more or less marked, flattened impressions slope towards the borders of the organ from the most prominent part of the anterior surface. One of these, on the upper and outer part of the kidney, is the **splenic impression**; another, extending downwards to the lower end of the kidney, is for the colon, or for the colon and jejunum; while the third, or **impressio gastrica**, corresponds to the position of the overlying stomach. The gastric impression occupies an area of the anterior surface of the left kidney, above and in the region of the hilum. Only a small portion of this impression is in direct contact with the stomach, since the pancreas and a part of the suprarenal capsule intervene between the stomach and the kidney (Fig. 803).

It is common to find the left kidney thicker and less flattened antero-posteriorly than the right, the impressions, or facets, upon its surface being at the same time better marked. With this probably is to be associated the fact that *floating kidney* is more rarely met with on the left than on the right side of the body.

**Extremities of the Kidney.**—The kidney, fixed and hardened *in situ*, is usually more pointed at its *lower* than at its *upper* end. The latter is more flattened from before backwards, and is wider from side to side. This flattened upper part of the kidney rests upon the diaphragm, and is bent somewhat forward.

**Renal Sinus** (sinus renalis). – The sinus of the kidney (Fig. 804), into which the hilum opens, is a narrow space, having its long axis corresponding to that of the kidney. The thick walls of the sinus cavity are formed by the substance of the kidney, and lined by a part of the fibrous kidney capsule which enters the sinus over the lips of the hilum. The floor of the sinus is not smooth, but presents a series of small projecting conical elevations called **renal papillæ** (papillæ renales), which vary from twelve to fifteen in number. Radiating from each papilla are a number of somewhat raised bars, or ridges, of kidney substance, separated by depressed areas. The blood-vessels and nerves enter and leave the kidney by piercing the wall of the sinus where it is formed by these little depressed areas (Fig. 804). The summit of each renal papilla is pierced by a number of minute openings called **foramina papillaria**, which are the terminal apertures of the secreting tubules, of which the kidney is mainly composed.

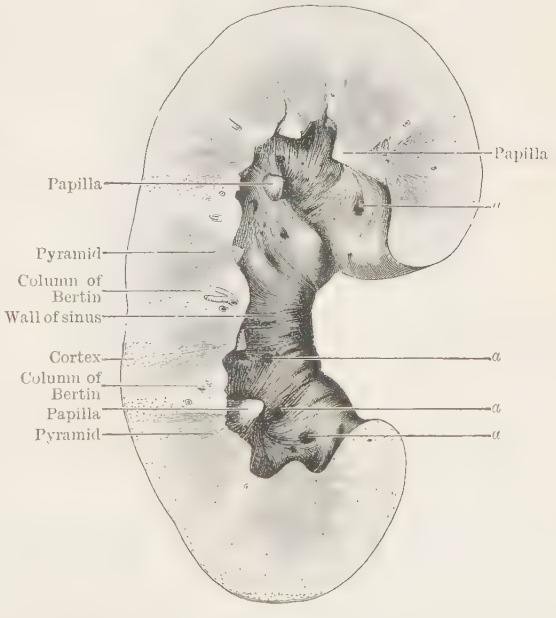

Fig. 804.—Longitudinal Section through the Kidney.

The vessels and fat have been removed to give a view of the wall of the kidney sinus. The points where the vessels enter the kidney substance are seen as little holes in the sinus wall at *a* and elsewhere.

The urine secreted by the kidney escapes through these foramina into the upper part of the ureter.

**Kidney in Section.**—Sections (Fig. 804) through the kidney show it to be, for the most part, composed of a number of pyramidal masses arranged with their bases towards the surface, while their apices project into the sinus of the kidney and form the renal papillæ already mentioned. These are termed the **medullary pyramids** (pyramides renales), and together constitute the **medulla** (substantia medullaris) of the kidney. They are more numerous than the papillæ, two or three usually ending in each papilla in the middle part of the kidney, and sometimes as many as six or even more in each papilla near the upper and lower ends of the organ. The bases of the pyramids do not reach the surface of the kidney, but are separated from it by a thin layer of kidney substance called the **cortex**, or **cortical part** of the kidney (substantia corticalis). The cortical substance not only covers over the bases of the pyramids, but also sends in prolongations, called **columns of Bertin** (columnæ renales), between the pyramids, towards the sinus. The medullary part of the kidney exhibits in section a striated appearance, while the cortical part is more granular and usually different in colour. The outer part of each pyramid, or the **intermediate zone** (basis pyramidis), as it is termed, appears in section to be composed of alternate dark and light streaks, while the inner, or **papillary part**, which is of a lighter colour, is more uniformly and faintly striated.

In sections of the kidney the larger blood-vessels are seen, after they have entered the kidney substance, to lie between the pyramids; some of their main branches are also visible passing across the bases of the pyramids.

In the fœtus and young child, and sometimes, though much less distinctly, in the adult, the surface of the kidney is marked by a number of grooves dividing it into polygonal areas. These represent the lobes (lobi renales) or "Renculi," of which the kidney is originally composed, and each corresponds to one papilla with its pyramids and surrounding cortical substance.

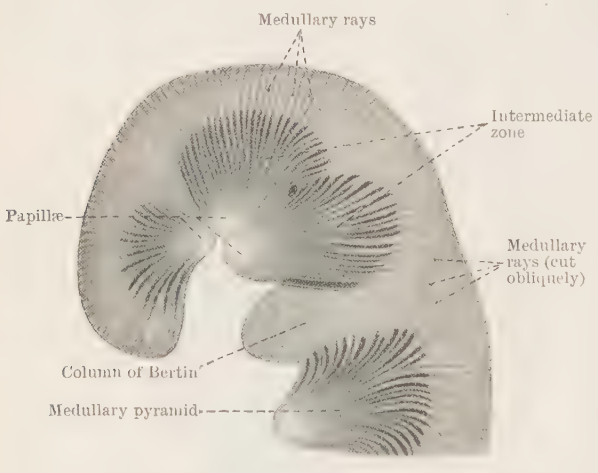

Fig. 805.—Section Through a Portion of the Kidney.

The darker parts separating the medullary rays, represent the labyrinth portion of the cortex.

An examination, with an ordinary pocket lens, of a section through the kidney shows that the lighter striæ of the intermediate zone are continued into the cortex. As they pass through the cortex towards the surface of the kidney they become less distinct, and appear, when cut longitudinally, as separate ray-like prolongations carried outward from the bases of the pyramids. These parts of the cortex, which seem in this way to be continuations of the medulla, are called **medullary rays** (pars radiata), and the portions of kidney cortex which intervene between them form the **labyrinth** (pars convoluta, Fig. 806). The appearance presented by the cortex of the kidney in section varies much according to the plane in which the section has been taken. If the section passes through, and lies parallel to the axis of a pyramid, the medullary rays, met with, will appear as isolated streaks directed from the base of the pyramid towards the surface of the kidney and separated from one another by narrow strips or intervals of labyrinth. On the other hand, in sections made at right angles to the axis of a pyramid, or cutting this axis obliquely, the labyrinth portion of the cortex presents the appearance of a continuous net the meshes of which are occupied by the medullary rays, and these latter now exhibit a circular or oval outline (Fig. 805). In a similar manner sections through the

intermediate zone differ much in the appearances they afford according to the plane in which they are cut.

**Kidney Tubules.**—The substance proper of the kidney is composed of an enormous number of minute tubules (tubuli renales), each of which has an exceedingly complicated course. The wall of a uriniferous tubule consists throughout of a basement membrane and of an epithelial lining, but the diameter of the tubule and the character of the epithelium vary much in the different parts. Each tubule begins in a thin-walled spherical dilatation, or **capsule** (capsula glomeruli), in which a complicated loop of capillary blood-vessels is contained. The tuft of capillaries is covered by a reflection of the delicate wall of the capsule, and is, as it were, invaginated into the capsule (Fig. 806). The capsules with their enclosed capillaries are often called **Malpighian corpuscles** (corpuscula renis), and are all placed in the labyrinth portion of the kidney cortex, where they may be recognised as minute red points just visible to the unaided eye and best marked when the renal vessels are congested. The tubule leading from the capsule—**first convoluted tubule**—is much convoluted, and lies within the labyrinth. Passing from the labyrinth, the tubule enters a medullary ray, in which its course becomes less complicated, and here it receives the name of **spiral tubule**. From the medullary ray the tubule enters the intermediate zone of the pyramid, and, diminishing in diameter, it pursues a straight course towards the apex of the pyramid, forming the so-called **descending limb of Henle's loop**. Within the apical portion of the pyramid the tubule suddenly bends upon itself, forming the **loop of Henle**, and reversing its direction, it passes back again through the intermediate zone into the medullary ray as the **ascending limb of Henle's loop**. This ascending limb exhibits a slight spiral twisting. Leaving the medullary ray, the tubule once more enters the labyrinth, where its outline becomes so uneven that the name **irregular tubule** is applied to it. While still within the labyrinth, its contour having acquired a more uniform appearance, the tubule receives the name of **second convoluted tubule**; this latter finally ends in a short **junctional tubule**, which passes back into a medullary ray and joins a **collecting tube**. Each collecting tube receives numerous kidney tubules, and pursues a straight course through a medullary ray and pyramid. Finally, several collecting tubes, uniting together, open as an **excretory tube**, by one of the foramina papillaria, on the surface of a renal papilla, into a calyx of the ureter (Fig. 806). In microscopic sections the various portions of the kidney tubule may be distinguished by the position which they occupy and by the character of the lining epithelium.

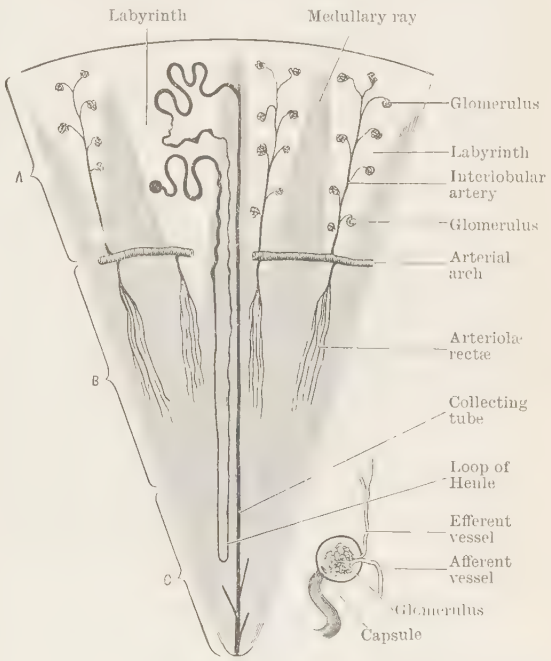

FIG. 806.—DIAGRAMMATIC REPRESENTATION OF THE STRUCTURES FORMING A KIDNEY LOBE.

In the middle part of the figure the course of one of the kidney tubules is indicated, and in the lateral parts the disposition of the larger arteries. A, Cortex; B, Intermediate zone; C, Papillary portion.

The diagram at the right-hand side of the lower part of the figure illustrates the connexions of the structures composing a Malpighian corpuscle.

**Connective Tissue of the Kidney.**—The tubules and the blood-vessels forming the substance of the kidney are all united together by a very small amount of connective tissue, which completely surrounds each tubule and blood-vessel and binds it to its neighbours. It has been found possible to obtain an accurate idea of the arrangement of this connective tissue by submitting thin sections of the kidney to the action of certain digestive fluids. When this is done the tubules and blood-vessels are removed, and the connective tissue stroma alone is left behind and is seen to form a continuous network, the spaces in which faithfully reproduce the outlines and the arrangement of the kidney tubules. The network of the stroma is continuous with the capsule of the kidney.

**Vessels of the Kidney.**—The renal artery is very large in proportion to the size of the organ to which it conveys blood. Its main branches, as they approach the kidney to enter the hilum, lie between the tributaries of the renal vein in front, and the ureter behind. Within the sinus of the kidney the branches of the renal artery become arranged in a dorsal and a ventral group, the dorsal vessels lying behind, the ventral ones in front of the subdivisions of the ureter. The ventral group of vessels supplies the part of the kidney which forms the anterior and outer walls of the sinus; the distribution of the dorsal group is for the most part restricted to the portion of the kidney which lies behind, and to the inner side of, the sinus. Entering the substance of the kidney in the manner described above (p. 1137), the larger arteries lie in the intervals between the pyramids, and are called the **interlobar arteries** (arteriæ interlobares renis). These vessels dividing, form a series of incomplete arterial arches (arteriæ arciformes), which pass across the bases of the pyramids. Although we speak of arterial arches, it must be understood that no anastomosis between the branches of the interlobar arteries actually takes place, but that each artery which enters the wall of the kidney sinus has an isolated distribution and possesses the characters of an end artery. From the arches two chief sets of branches come off—those of one set are continued towards the periphery and enter the labyrinth, while those of the second set pursue a recurrent course and enter the intermediate zone of the medulla. The latter vessels, called **arteriolæ rectæ**, give rise to the coarsely-striated appearance which this part of the kidney exhibits in section. Each of these vessels, entering the medulla, divides into a number of fine branches which run nearly parallel to one another, and supply the tubules in this region of the kidney. The vessels directed outwards, or **interlobular arteries** (arteriæ interlobulares), pass through the labyrinth towards the surface of the kidney. They give off a number of short branches, termed **vasa afferentia**, each of which proceeds to the dilated extremity, or capsule, of a uriniferous tubule. Here the vas afferens breaks up into a much convoluted capillary mass, called a **glomerulus**, which is contained within the invagination of the capsule. The little vein which issues from the glomerulus, or **vas efferens**, instead of running directly into a larger vein breaks up, after the manner of an artery, into capillaries which supply the tubules of the labyrinth and medullary rays. Hence almost all the blood which supplies the tubules of the cortical part of the kidney passes in the first instance through the glomeruli. Some of the tubules of the intermediate zone also receive their blood-supply through vasa efferentia derived from the glomeruli which lie near. These little vessels passing from glomeruli into the intermediate zone of the medulla accompany the arteriolæ rectæ and are sometimes spoken of as false arteriolæ rectæ.

The fibrous capsule of the kidney receives minute branches from the interlobular arteries, some of which, piercing the capsule, communicate by capillaries with the vessels of the tunica adiposa.

Veins corresponding to the interlobular arteries and arteriolæ rectæ collect the blood from the capillaries surrounding the tubules, and unite to form a series of complete arches across the bases of the pyramids. From these venous arcades vessels arise, which traverse the intervals between the pyramids and reach the sinus of the kidney, where they unite to form the dorsal and ventral tributaries of the renal vein. Some small veins in the superficial part of the cortex communicate through the fibrous capsule with minute veins in the tunica adiposa.

**Nerves of the Kidney.**—The nerves of the kidney accompany the branches of the artery, and issue from the renal plexus.

From clinical evidence it would appear that the nerve fibres which reach the kidney are derived from the tenth, eleventh, and twelfth thoracic nerves. The minute branches of the nerves form regular net-like plexuses on the walls of the fine arteries and kidney tubules, and the presence of nerve terminations occurring among the epithelial cells lining the tubules has recently been demonstrated.

**Variations.**—A marked difference in the size of the two kidneys is sometimes observed, a small kidney on one side of the body being usually compensated for by a large kidney on the opposite side. Cases of complete absence of one or other kidney are recorded.

Traces of the superficial lobulation of the kidney, present in the fœtus and young child, are often retained in the adult.

**Horse-shoe kidney** is not an infrequent abnormality. In these cases the two kidneys are united at their lower ends, across the middle line, by a connecting piece of kidney substance. The amount of fusion between the two kidneys varies much; it is sometimes very complete, while in other cases it is but slight, the connexion being chiefly composed of fibrous tissue.

In very rare cases the kidney appears to be almost entirely surrounded by peritoneum and to be attached to the abdominal wall by a kind of mesentery, enclosing the vessels and nerves passing to the hilum. The condition is believed to be congenital.

Not very infrequently one or both kidneys are found at a much lower level than usual, and occupying a position in the iliac fossa or the pelvic cavity. This condition, when congenital, is associated with an arrest in the normal change in position, relative to surrounding structures, which the kidney experiences during development. In such cases the kidney does not receive its blood supply from usually placed renal arteries, but from vessels which arise from the lower end of the aorta, or from the iliac, or the middle sacral artery. These congenitally abnormally situated kidneys do not usually possess the typical outline of the normal organ, but vary much in shape, and the hilum is often directed downwards and not inwards.

In some mammalian animals, such as the bear, the ox, the porpoise, etc., the kidneys are composed of a number of completely isolated lobes, each of which corresponds to one papilla, its pyramids and surrounding cortex; while in others, such as the horse, the fusion of the lobes is more complete even than in the human kidney, and a single mass represents the united papillæ.

## The Duct of the Kidney.

The duct of the kidney begins above in a thin-walled funnel-shaped expansion called the **pelvis** (pelvis renalis), placed partly within and partly outside the sinus of the kidney. Towards the level of the lower end of the kidney the part of the pelvis which lies outside the sinus diminishes in calibre, and forms a tube termed the **ureter** (Fig. 807).

**Pelvis of the Kidney.**—Within the sinus of the kidney the pelvis lies for the most part behind the larger renal vessels, and is formed by the junction of two, or more rarely three, thin-walled tubes (calyces majores), each of which has a number of branches. These latter, called **infundibula**, or **calyces** (calyces renales), are short, and increase in diameter as they approach the sinus wall. Their wide, somewhat funnel-like ends enclose the renal papillæ, the secretion from which they receive and conduct to the pelvis. The calyces are usually about twelve in number, one calyx sometimes surrounding two or even three papillæ. The portion of the pelvis that lies outside the kidney has in front of it, in addition to the renal vessels, on the right side the second part of the duodenum, and on the left side a part of the pancreas and sometimes the duodeno-jejunal flexure (Fig. 794).

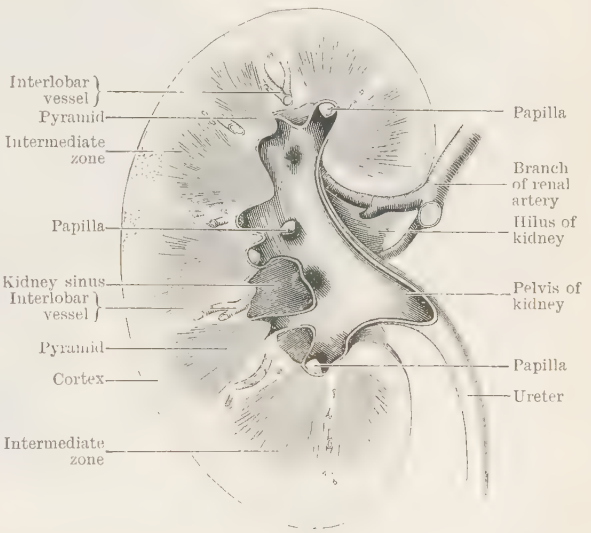

Fig. 807.—Longitudinal Section of the Kidney, opening up the Kidney Sinus.

The pelvis of the ureter and some of its calyces have been laid open as they lie within the sinus.

**Ureter.**—The ureter is the vessel which carries the urine from the pelvis of the kidney to the bladder. It is a pale-coloured thick-walled duct with a small lumen. While *in situ* it has a total length of about ten inches, and lies throughout its whole course behind the peritoneum, to which it is closely connected, in the sub-peritoneal tissue. In its upper part the ureter lies in the abdominal cavity, and in its lower part in the pelvic cavity (Figs. 796, 794, and 808).

The normal ureter, in the flaccid condition, measures after its removal from the body eleven to fourteen inches.

The **abdominal portion** of the ureter (pars abdominalis), about five or five and a half inches in length, is directed downwards and slightly inwards, and lies upon the psoas muscle. Certain structures are related to the ureters in a similar manner on each side of the body; for instance, the abdominal portion of each ureter is crossed very obliquely, on its anterior aspect, by the spermatic or ovarian vessels, and behind each duct the genito-crural nerve passes downwards and outwards. Other

structures are related to the duct of the right or left side alone; on the **right side** the descending, or second, part of the duodenum lies in front of the upper part of the ureter, and the line of attachment of the mesentery crosses it lower down, just before the vessel enters the pelvic cavity. On the **left side** of the body the line of attachment of the mesentery of the pelvic colon crosses the ureter.

Crossing the common iliac, or the external iliac artery, the ureter enters the pelvis. The left ureter more usually crosses the common iliac artery, the right vessel in most cases lies across the external iliac, but this arrangement is by no means constant.

The **pelvic portion** of the ureter (pars pelvina) is about four or four and a half inches in length, and passes downwards on the side wall of the pelvis, immediately beneath the peritoneum, describing a curve which is convex backwards and outwards (Fig. 808). The most convex portion of this curve lies close to the deepest

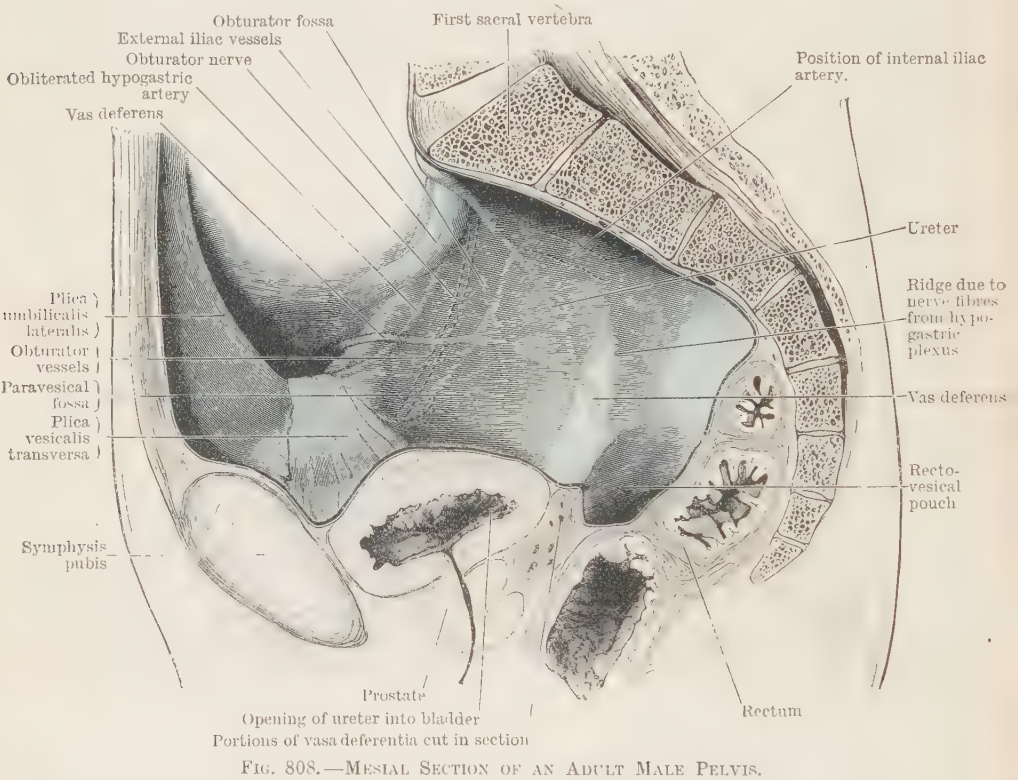

FIG. 808.—MESIAL SECTION OF AN ADULT MALE PELVIS.

The coils of the small intestine which lay within the pelvis have been lifted out in order to give a view of the side wall of the pelvic cavity. The peritoneum is coloured blue. The separation of the bladder from the prostate is indicated somewhat diagrammatically.

part of the great sciatic notch (Figs. 831 and 854). In its course within the pelvis the ureter lies in front of the internal iliac artery, and crosses the inner aspect of the obturator nerve and vessels and of the obliterated hypogastric artery. About the level of the ischial spine the ureter bends somewhat inwards above the fascia of the pelvic floor, to reach the bladder, and in this position it is crossed on its inner side by the vas deferens. A little further on in its course the ureter comes into relationship with the upper end of the vesicula seminalis, in front of which it lies as it pierces the bladder wall. The ureter, as it passes inwards to the bladder, is placed on an anterior and deeper plane than the vas deferens, and is surrounded by a dense plexus of veins, connecting the vesical and prostatic plexuses with the internal iliac vein. When the right and left ureters reach the bladder they are a little more than two inches apart and they pierce the bladder wall very obliquely, lying embedded within its muscular tissue for nearly three quarters of an inch of their length. Finally, they open into the bladder by two small slit-like

apertures which are of a valvular nature, and prevent a backward passage of fluid from the bladder. It is probable, however, that an exaggerated idea of the valvular nature of the openings of the ureters into the bladder is obtained by an examination of the parts in the dead subject. When the bladder is empty the openings of the ureters are placed at about one inch apart, but when that viscus is distended they are often two inches, or more, distant from one another. As the ureter pierces the bladder-wall the muscular fibres of the bladder and ureter remain quite distinct, and so the ureter, remaining a thick-walled tubular structure, appears to pass through a gap in the muscular wall of the bladder. The mucous coat alone of the ureter becomes continuous with that of the bladder.

The triangular district on the side wall of the pelvis, which is bounded behind by the ureter, below by the vas deferens, and above by the external iliac vessels and pelvic brim, is called the obturator fossa.

The canal of the ureter is not uniform throughout but is somewhat constricted in certain places, corresponding to the regions where the ureter is most sharply curved, or changes its direction. These more constricted parts of the tube are described as occurring one in the middle of the abdominal portion, one at the junction of abdominal and pelvic portions, and one in the pelvic part of the ureter. Also just before the ureter joins the pelvis of the kidney and just as it reaches the bladder wall its lumen is usually somewhat constricted.

**In the female**, the ureter, near its termination, passes beneath the lower part of the broad ligament of the uterus and lies to the outer side of the cervix uteri and upper part of the lateral wall of the vagina. It is accompanied in the lower part of its course by the uterine artery, which crosses it on its anterior aspect not far from its termination. Higher up it lies in the peritoneal ridge which forms the posterior and lower boundary of the fossa ovarica, a posterior subdivision of the obturator fossa (Fig. 824).

**Structure of the Ureter.**—The wall of the ureter is thick and of a whitish colour and is composed of mucous, muscular, and fibrous coats. The **mucous coat** (tunica mucosa) of the ureter possesses an epithelium composed of many layers of cells, those nearest the surface being of large size. When the canal is empty the mucous coat is thrown into numerous longitudinal folds, and so its lumen exhibits a stellate outline in transverse section. The submucous tissue varies much in thickness in different parts of the ureter and contains some elastic fibres. The unstriated muscle fibres which compose the **muscular coat** (tunica muscularis) are collected into bundles which are separated by a considerable amount of connective tissue and are arranged, some longitudinally, some circularly. In the upper part of the ureter a relatively large amount of connnective tissue is present deep to, and among the bundles of muscle fibres which are arranged in three distinct strata—an inner longitudinal, an intermediate circular, and an outer longitudinal. In the middle part of the vessel the same layers may be recognised, but the circularly disposed bundle of fibres are more numerous than higher up. In the lower part of the ureter the connective tissue is relatively scanty and the inner longitudinal fibres lie close to the lining epithelium; in this region also the longitudinal folds of the mucous coat become fewer and less marked. A short distance above the point where it reaches the bladder, the wall of the ureter becomes much thickened by the addition of a number of coarse bundles of longitudinally arranged muscle fibres, which are applied to the outer surface of the muscular coat. These muscle fibres form the so-called "sheath of the ureter," and are continued on the superficial aspect of the vessel as it passes through the bladder wall. In the portion of the ureter which traverses the wall of the bladder (pars intramuralis) nearly all the fibres of the muscular coat are disposed longitudinally or in a direction parallel to that of the vessel. The muscle fibres lie close beneath the epithelium, and end just where the mucous coats of the bladder and ureter become continuous. The outer **fibrous coat** (tunica adventitia) of the ureter varies in thickness at different levels, and in its lower part blends with the connective tissue, which lies among the muscle fibres forming the sheath of the ureter just mentioned above.

The mucous membrane of the calyces and of the pelvis of the kidney possesses an epithelium resembling that of the ureter. Where each renal papilla projects into one of the calyces a deep circular recess, or fornix, is formed between the wall of the calyx and the sloping side of the papilla; at the bottom of this recess the epithelium of the calyx becomes continuous with that covering the papilla. At the formina papillaria the epithelium joins that of the kidney tubules. The muscular fibres in the wall of the calyces and of the pelvis are collected into loosely arranged bundles separated by wide intervals occupied by fibrous connective tissue. As in the ureter, the outermost and innermost fibres run in a longitudinal, the intermediate ones in a circular direction. The circularly arranged fibres alone form a distinct layer.

The abdominal part of the ureter receives its blood supply from the renal and spermatic arteries; the pelvic portion is supplied by the superior vesical and middle hæmorrhoidal vessels.

The nerves of the ureter reach it through the renal, the spermatic, and the hypogastric plexuses.

**Variations.**—The ureter is sometimes represented by two tubes in its upper portion. In rarer cases it is double throughout the greater part of its extent, or even its whole length from the pelvis of the kidney to the bladder. In such cases there may be two openings into the bladder. Asymmetry as regards such abnormalities is very common.

Variations in the form of the pelvis of the kidney are of frequent occurrence. Most usually the pelvis divides into two large subdivisions, one of which passes in the direction of the upper, the other in that of the lower pole of the kidney. In some cases these branches come off directly from the ureter without the intervention of a pelvis, or a subdivision may lead to the formation of two pelves.

## THE BLADDER.

The **bladder** (vesica urinaria) is a hollow muscular organ situated in the anterior part of the pelvic cavity, behind the symphysis pubis. It lies in front of the rectum, from which it is separated *in the male* by the seminal vesicles and the terminal portions of the vasa deferentia, and *in the female* by the vagina and uterus. The bladder wall is chiefly composed of muscular tissue, and its thickness and the size of the contained cavity depends on the amount of fluid within the organ. The right and left ureters which convey the fluid secreted by the kidneys open into the lower and under part of the bladder about half an inch from the mesial plane; also the urethra, or canal by which the urine reaches the surface, opens into the bladder, its aperture lying in the middle line of the under part of the bladder wall, not far from the openings of the ureters, but on a lower and anterior plane. The size and shape of the bladder, and also to a great extent its relations, vary with the amount of distension, or contraction, of the organ. When the bladder is empty, or only slightly distended, it lies within the pelvic cavity; as it becomes filled with urine it rises above the pubis, and, crossing the pelvic brim, enters the abdominal cavity. These changes affect chiefly the upper part of the bladder, which becomes altered in shape and size, and acquires new connexions and relations; the lower portion varies but slightly with the amount of distension of the organ (see Figs. 809 and 810). The position occupied by the bladder depends, to a certain extent, on the condition of the rectum, for when the lower part of the rectum is distended, the bladder as a whole is thrust somewhat upwards and forwards. The upper part of the bladder is covered by peritoneum, which is reflected on to it from the anterior abdominal wall in front, from the sides of the pelvis laterally, and, *in the male*, across the seminal vesicles and terminal parts of the vasa deferentia from the rectum behind. *In the female* the peritoneum passes on to the bladder posteriorly from the anterior surface of the uterus. The peritoneum dips down posteriorly for a certain distance between the bladder and rectum in the male, forming the recto-vesical or recto-genital pouch; in the female a slit-like peritoneal depression, called the utero-vesical pouch, intervenes between the anterior surface of the uterus and the bladder (Fig. 818). The under part of the bladder which lies below the peritoneum is for the most part directed towards the pelvic floor. In the middle line it is supported by the symphysis pubis and the

retro-pubic pad of fat; further back *in the male* it rests upon the prostate and on the lower part of the rectum, from which latter it is separated by the vesiculæ seminales and the terminal parts of the vasa deferentia. *In the female* it rests upon the anterior wall of the vagina. Laterally the bladder is supported by the

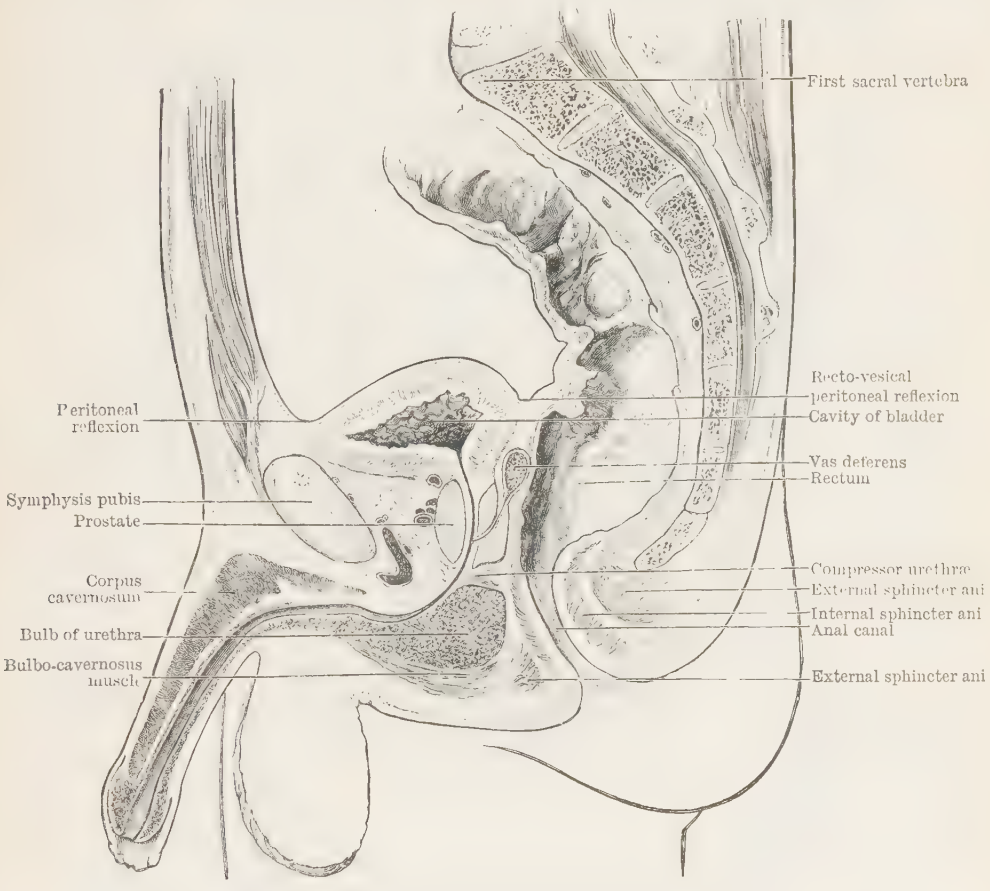

FIG. 809.—MESIAL SECTION THROUGH THE MALE PELVIS.

The bladder contains but a small amount of fluid. The separation between the bladder and prostate is shown somewhat diagrammatically. Drawn from a preparation in the Anatomical Department, Trinity College, Dublin.

levatores ani muscles, and further from the middle line it is in contact on each side with the obturator internus; it is separated from both of these muscles by a layer of the pelvic fascia.

The opening of the urethra, or **internal urethral orifice** (orificium urethræ internum), is placed in or near the part of the bladder wall which lies lowest in the pelvic cavity. The term **neck** or **cervix**, is often applied to this region, the bladder appearing as if it were suddenly constricted here to form the urethra. The portion of the bladder wall behind the urethral orifice, which is directed *in the male* towards the anterior wall of the rectum and lies below and in front of the recto-vesical pouch, is called the **base** of the bladder (fundus vesicæ); it is closely related to the seminal vessels and ampullæ of the vasa deferentia. The corresponding part of the bladder *in the female* rests against the anterior wall of the vagina. The term **apex**, or **summit** of the bladder (vertex vesicæ) is applied to the portion which lies nearest to the upper border of the symphysis when the organ is empty, and rises high above the pubis into the abdominal cavity when the bladder is distended. Connected with the apex of the bladder is a fibrous cord (ligamentum umbilicale medium) which passing upwards, in the middle line, on the posterior aspect of the anterior abdominal wall reaches the umbilicus, and represents the

**urachus**, or portion of the allantois retained within the body of the developing embryo. The part of the bladder connecting the apex with the base, and not sharply marked off from either, is called the **body**, or **corpus vesicæ**.

**Position of the Urethral Orifice.**—During the various changes in shape and size which the bladder undergoes, the region of the urethral orifice remains almost

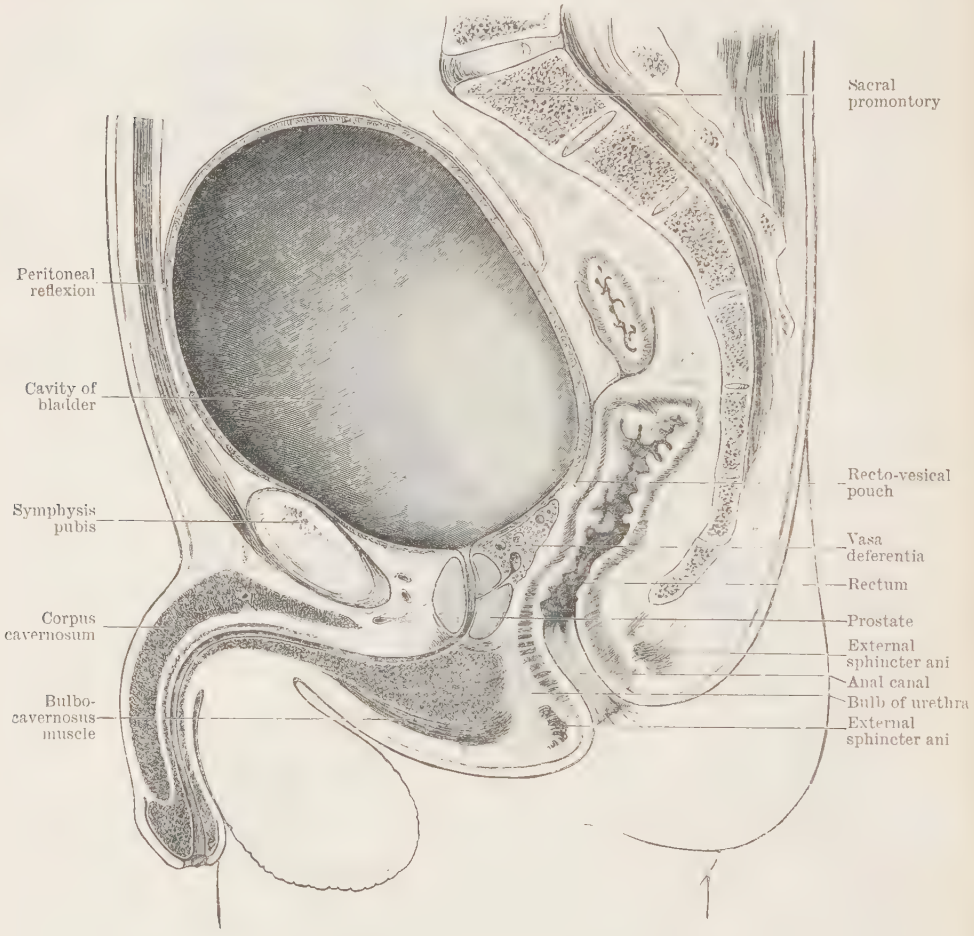

FIG. 810.—MESIAL SECTION OF THE MALE PELVIS.

The bladder has been artificially distended. From a specimen in the Anatomical Department, Trinity College, Dublin.

fixed in position. The comparatively slight variations in the level of the internal urethral orifice which do occur, depend partly upon the quantity of fluid contained in the bladder, and partly upon the amount of distension of the lower portion of the rectum. When the bladder is very much distended this region lies at a slightly lower level in the pelvis than it does when the organ is empty; and, on the other hand, distension of the lower part of the rectum raises, to some extent, the level of the urethral orifice. The urethral orifice lies immediately above the prostate, and behind and slightly below the level of the upper margin of the symphysis pubis, from which it is distant about two to two and a half inches. It can be easily reached by a finger introduced into the bladder through the abdominal wall above the symphysis pubis. It is usually placed half an inch to one inch above the level of a plane passing through the lower margin of the symphysis and the lower end of the sacrum, but in some cases it is found to be somewhat lower. In the female it normally occupies a lower level than in the male. Since the position of the internal urethral orifice varies, in the manner above described, with the condition of the rectum and of the bladder itself, it follows that it lies at its lowest limit

when the bladder is full and the rectum empty, and at its highest level when the bladder is empty and the rectum distended.

**Under Aspect of the Bladder.**—The lower part of the bladder, which is directed towards the pelvic floor, changes, as we have seen, but slightly with the varying amount of distension of the viscus. When the organ has been carefully hardened before its removal from the body, it is possible to map out on its under aspect three convex triangular areas, which may be distinguished from one another by the directions in which they look. The three areas approach one another in the region of the urethral orifice, where, in the male, a portion of the under aspect of the bladder wall is structurally continuous with the upper part of the prostate. Behind the urethral orifice is a triangular district, directed downwards and backwards, and related, *in the male*, to the seminal vesicles and the terminal portions of the vasa deferentia which, together with the recto-vesical layer of the pelvic fascia, intervene in this position between the bladder and the rectum. This triangular area of the bladder wall is known as the **base**, or **postero-inferior surface** of the bladder, and *in the female* it is directed against the anterior wall of the vagina. The rest of the under aspect of the bladder is formed by two **infero-lateral areas**, or surfaces, which meet in the middle line in front of the urethral orifice, and are directed for the most part downwards and outwards (see Fig. 811). Each of these areas extends backwards to join the postero-inferior surface, or base, along a rounded border which lies between the point where the ureter reaches the bladder and the urethral orifice. The infero-lateral part of the bladder wall rests against the fascia covering the levator ani and the obturator internus muscles, and, nearer the middle line, upon the pubes and retro-pubic pad of fat.

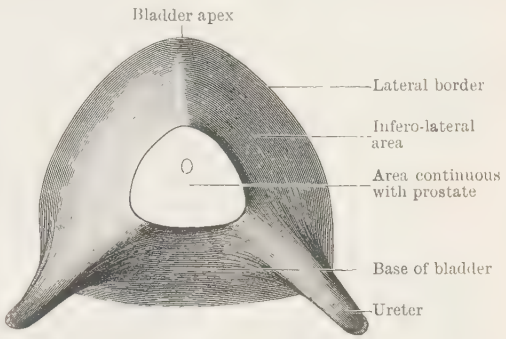

FIG. 811.—UNDER ASPECT OF THE EMPTY MALE BLADDER from a subject in which the viscera had been hardened *in situ*.

The prostate has been severed from the bladder, and the white area in the drawing indicates the position where the two structures were continuous.

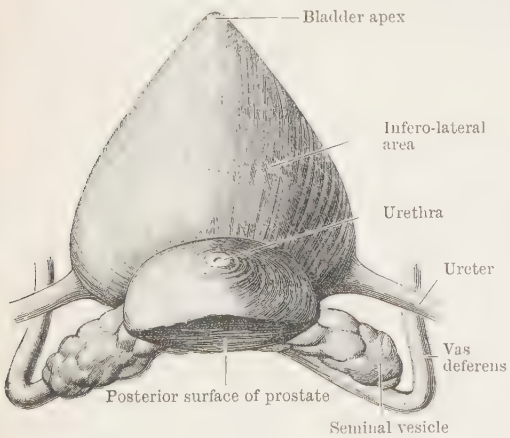

FIG. 812.—THE BLADDER, PROSTATE, AND SEMINAL VESICLES, VIEWED FROM BELOW.

Taken from a subject in which the viscera were hardened *in situ*. Same specimen as figure 813, A. The bladder contained but a small amount of fluid.

The three rounded borders which mark off the three triangular areas on the under aspect of the bladder, just described, extend from the region of the urethral orifice to the bladder apex, and to the points where the ureters reach the bladder wall (see Fig. 811).

**Shape and Relations of the Empty Bladder.**—When the bladder is empty, or nearly so, it has, roughly speaking, the shape of an inverted tetrahedron, whose apex corresponds to the point where the urethra leaves the organ, while the base of the tetrahedron is formed by the superior surface of the bladder. The three basal angles of the tetrahedron correspond to the bladder apex and to the two **lateral angles** of the bladder, or points where the ureters join the organ. The three surfaces, which meet inferiorly at the urethral orifice, are only marked off from one another by rounded borders, but as long as the organ is empty, or nearly so, they are separated by distinct borders from the superior surface. These three areas have been already described as the infero-lateral surfaces and the base of the bladder (Figs. 811 and 812). Their relations have also been indicated. The

**superior surface** of the empty bladder looks upwards into the pelvic cavity; it is convex when the organ is contracted, concave when relaxed. This surface is covered by peritoneum, and its outline, which is approximately triangular, is determined by lateral and posterior borders (Fig. 829). The **lateral borders** of the empty bladder are sharply marked, and extend from the bladder apex to the lateral angles of the bladder, or points where the ureters join the organ. They separate the superior surface from the infero-lateral portions of the under aspect of the bladder wall (Fig. 813, A). The **posterior border** stretches across between the lateral angles of the bladder, and separates the superior from the basal surface of the viscus. The superior surface is related in the male to coils of intestine; in the female it is also related to the anterior surface of the uterus. The lateral border of the empty bladder lies against the pelvic fascia just above, or at the level of the upper limit of the levator ani muscle. The vas deferens crosses the side wall of the pelvis

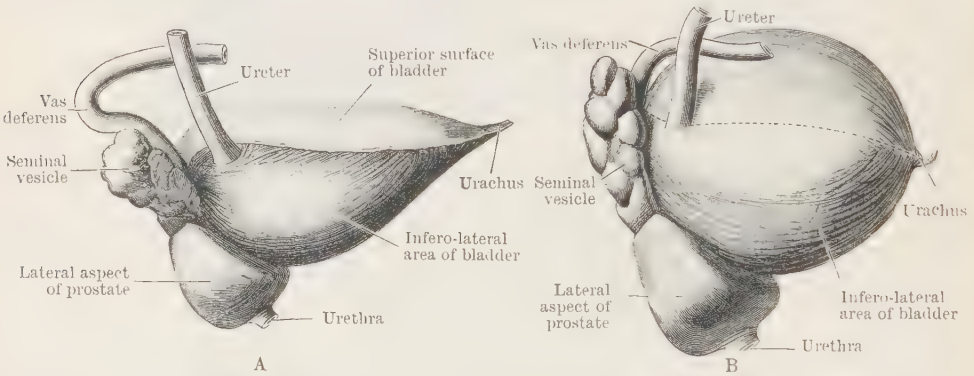

FIG. 813.—THE BLADDER, PROSTATE, AND SEMINAL VESICLE, VIEWED FROM THE OUTER SIDE.

Drawn from specimens in which the viscera were hardened before removal from the body. In A the bladder contained but a very small quantity of fluid; in B the quantity was somewhat greater. In A the peritoneum is shown covering the upper surface of the bladder, and its cut edge is seen where it is reflected along the lateral border of the organ. In B the level of the peritoneal reflexion is indicated by a dotted line.

parallel to it, but at a considerably higher level. In mesial section the cavity of the empty and relaxed bladder often presents the appearance of a Y-shaped chink, the stem of the Y being represented by the urethra as it leaves the organ, and the two limbs by the narrow intervals between the superior surface and the under parts of the bladder wall which lie in front of and behind the urethral orifice. This relaxed form is sometimes described as the diastolic condition of the empty bladder, and is found associated with a bladder wall of but little thickness, and a concave upper surface. The condition is usually the result of an escape of fluid after death, when the bladder wall has lost the power of contracting. It certainly does not represent a normal condition of the organ in the living. The normal empty bladder is strongly contracted, and its wall is thick and firm. A distinctly Y-shaped appearance is not presented by its cavity in mesial section, but the interior of the organ is seen as a simple narrow interval continuous with the canal of the urethra.

**Distended Bladder.**—As the bladder fills with fluid the superior wall is raised upwards from the intero-lateral and basal walls, and, at the same time, the borders separating the superior from the other surfaces of the bladder become at first more rounded and then obliterated. The lateral borders of the bladder, becoming in this manner opened out, give rise to so-called **lateral surfaces** in the distended organ. These surfaces, however, are not sharply marked off, and are directly continuous with the superior surface. During distension, also, the angles present in the empty condition of the organ become rounded as the entire bladder wall becomes more uniformly convex. The general shape of the bladder becomes altered during distension — from the tetrahedral form of the empty organ, already described, the bladder as it becomes filled assumes first a somewhat spherical, then an oval contour. During distension the enlarging

bladder comes to occupy more and more of the pelvic cavity, displacing upwards the portions of the colon and small intestine which may lie in the pelvis when the organ is empty. Until all the available pelvic space has been filled up, the form of the distended bladder is oval, with the larger end directed downwards and back-

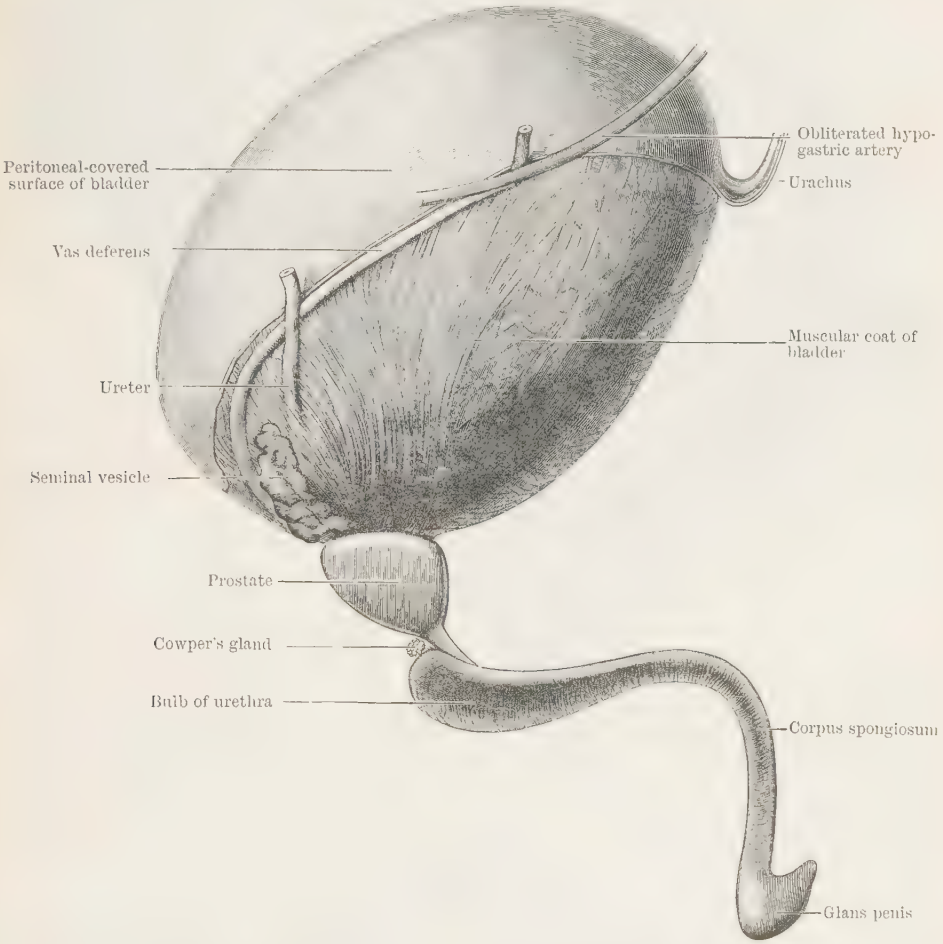

FIG. 814.—THE BLADDER AND THE STRUCTURES TRAVERSED BY THE URETHRA IN THE MALE, viewed from the outer side. The bladder has been artificially distended.

wards; but when the pelvic wall prevents further expansion, the portion lying above the pelvic brim being more free to enlarge, the outline of the organ may become an oval with the larger end directed upwards and forwards into the abdominal cavity (compare Figs. 815, 810). The highest part of the distended bladder lies at some distance above the pelvic brim, and does not correspond to the attachment of the urachus at the apex, but to a point further back (Fig. 814). As the superior wall of the bladder is raised up during distension it carries with it the peritoneum, and thus the reflexion of that membrane, from the anterior abdominal wall on to the apex of the bladder, comes to lie one and a half inches, or even higher, above the upper margin of the symphysis pubis (Fig. 810). It is, therefore, possible to puncture, or open into the distended bladder, through the anterior abdominal wall above the symphysis pubis, without at the same time opening into the peritoneal cavity. In a similar manner the line of reflexion of the peritoneum, from the side wall of the pelvis on to the lateral aspect of the bladder, is raised higher during distension, and may come to correspond, in part, to the level of the vas deferens, or to that of the obliterated hypogastric artery (Figs. 814 and 816). On the other hand, the level of the reflexion of the peritoneum from the rectum towards the basal aspect of the

bladder does not appear to vary much with the distension, or contraction, of the organ (compare Figs. 809 and 810), and thus the fossa between the bladder and rectum

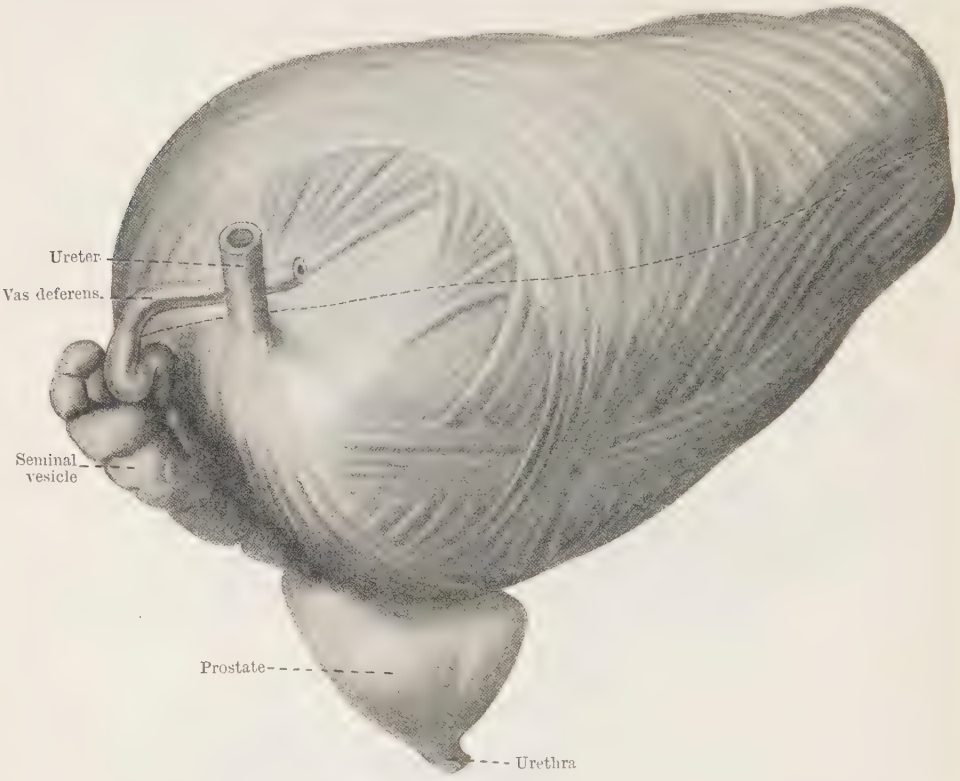

FIG. 815.—LATERAL ASPECT OF BLADDER CONTAINING TEN OUNCES OF FLUID. (Normally distended.)
The dotted line indicates the line along which the peritoneum was reflected from the organ.

becomes relatively very deep when the bladder is full. The bladder in normal distension may contain as much as one pint, but in most cases the organ is emptied

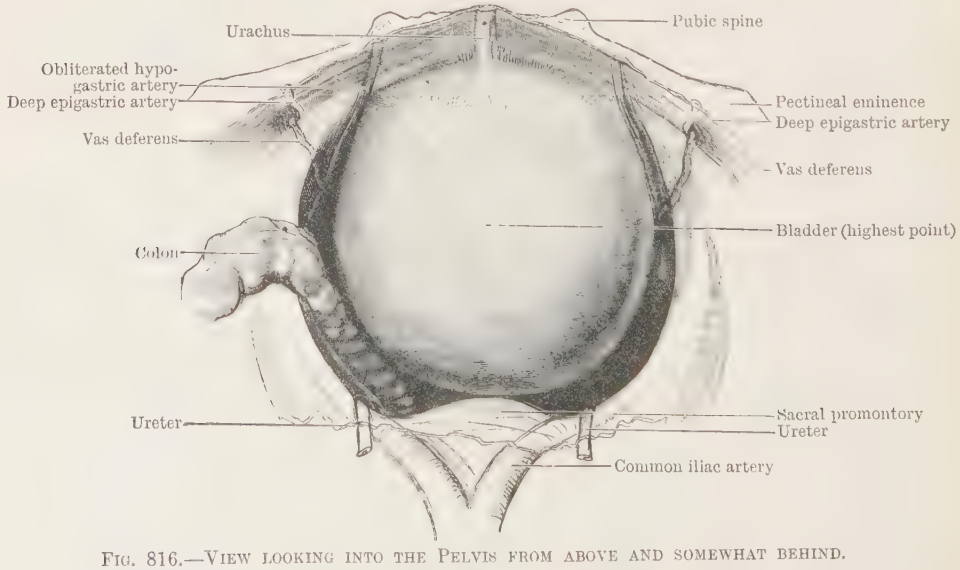

FIG. 816.—VIEW LOOKING INTO THE PELVIS FROM ABOVE AND SOMEWHAT BEHIND.
The bladder has been artificially distended.

when its contents reach from six to ten ounces. Under abnormal, or pathological, conditions the bladder capacity may be much increased.

**Varying Relationships, according to the degree of Distension of the Bladder.**—When the bladder is distended the obliterated hypogastric artery may cross forwards against its side, when empty the obliterated vessel where nearest often lies as much as one and a quarter inches above the lateral border of the organ (Figs. 808 and 814). The vas deferens, during a part of its course, is in contact with the side wall of the distended bladder, but lies when the organ is empty above and parallel to the lateral border, only coming into relationship with the basal surface of the bladder beyond the point where it crosses the ureter. The side wall of the distended bladder is closely related to the obturator vessels and nerves.

**Interior of the Bladder.**—The mucous membrane lining the bladder is loosely connected to the muscular coat, and when the bladder is contracted the mucous lining is thrown into a number of prominent wrinkles or folds (Fig. 817). At one place only the mucous membrane is firmly connected to the subjacent muscular coat, and the inner surface of this part of the bladder wall is smooth and free from wrinkles. This smooth area, called the **trigonum vesicæ**, corresponds to a triangular surface behind the urethral orifice and to the part of the bladder wall which immediately surrounds the opening. The apex lies at the beginning of the urethra, and the base of the triangle is formed by a line drawn between the openings of the ureters into the bladder. Just behind the urethral opening the bladder wall sometimes bulges slightly into the cavity, owing to the presence beneath it of the middle lobe of the prostate. When well marked, as it often is in old people, this elevation is termed the **uvula vesicæ**. Stretching across between the openings of the ureters there is usually to be seen a smooth ridge, which is due to the presence of a bundle of transversely-disposed muscle fibres, within this part of the bladder wall, beneath the mucous membrane. This ridge, which may be deficient near the middle line, has been called the "torus uretericus," and curved so as to be convex forwards. The lateral portions of the ridge which lie outside the openings of the ureters are called the **plicæ uretericæ**, and are produced by the terminal parts of the ureters as they traverse the bladder wall and lie beneath the mucous coat of the bladder (Fig. 817). In old people the region behind the trigonum is usually distinctly depressed and forms a shallow fossa, sometimes called the retro-ureteric fossa. A less distinct shallow depression may sometimes be observed on each side of the trigone. Round the urethral orifice are a number of minute radially-disposed folds which, disappearing into the urethra, become continuous with the longitudinal folds of the mucous membrane of the first part of that canal. The ureters pierce the bladder wall very obliquely, and so the minute opening (orificium ureteris) of each has an elliptical outline. The outer boundary of each opening is formed by a thin, crescentic fold, which, when the bladder is artificially distended in the dead subject, acts as a valve in preventing water or air from entering the ureter. Hence the term "valvula ureteris" is sometimes used to designate the fold. In the empty bladder the urethral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle, whose sides are about one inch in length. When the bladder is distended, the distance between the openings may be increased to one and a half inches or more.

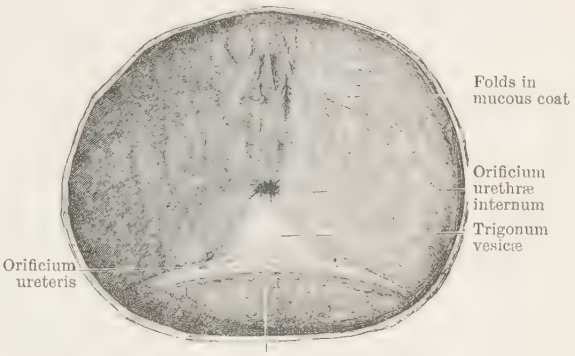

FIG. 817.—VIEW OF THE INTERIOR OF THE BLADDER IN THE REGION OF THE URETHRAL ORIFICE.

**Bladder in the Female.**—In the female the bladder is related behind to the uterus and upper part of the vagina. The anterior surface of the uterus in its upper part is separated from the upper surface of the bladder by the shallow utero-vesical pouch of peritoneum, but the two organs are nevertheless normally in apposition. So close is this relationship that the upper surface of the bladder very

often shows a slight concavity, due to contact with the convex anterior wall of the

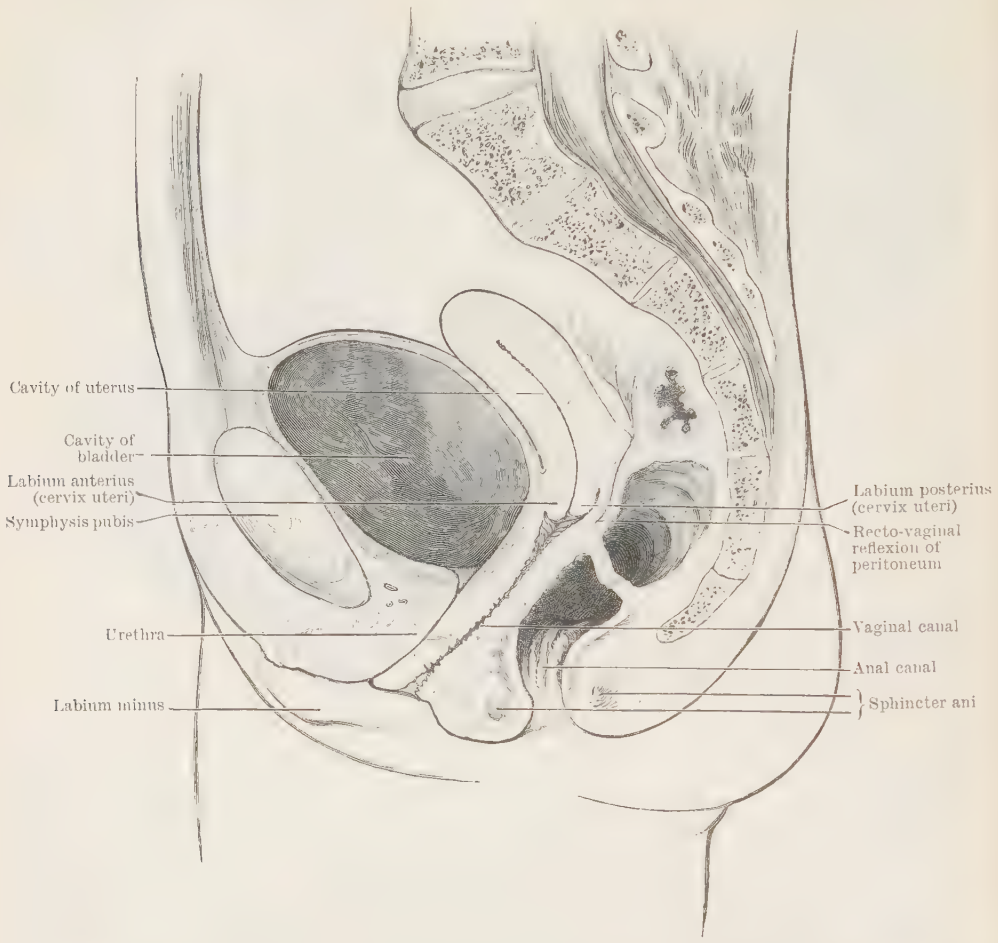

FIG. 818.—MESIAL SECTION OF THE PELVIS IN AN ADULT FEMALE.

The cavity of the uterus is indicated diagrammatically From a specimen in the Anatomical Department, Trinity College, Dublin.

uterus. The lower part of the uterus and upper part of the vagina are not separated by peritoneum from the basal surface of the bladder, but are in actual apposition with it (Fig. 818). Thus, below the level of the utero-vesical pouch, the female bladder is related in much the same manner to the uterus and anterior wall of the vagina as the male bladder is related to the vesiculæ seminales and vasa deferentia. The apex of the bladder, where the urachus is attached, often lies on a lower level than in the male, so that the organ, even when distended, rises less freely into the abdomen. The bladder as a whole is placed deeper in the pelvis than in the male, and the internal urethral orifice lies just above or just below a line drawn from the lower margin of the symphysis to the lower end of the sacrum (p. 1146). The lower level of the internal urethral orifice is probably corre-

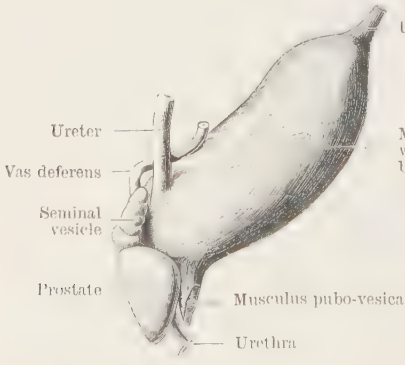

FIG. 819.—THE BLADDER OF A NEWLY-BORN MALE CHILD, viewed from the outer side.

The drawing is from a specimen which had been hardened *in situ*.

lated with the absence of the prostate in the female. It is probable that as regards capacity no difference exists between the bladder in the male and in the female; the conflicting results arrived at by different observers are probably due to the faulty methods which have been employed in estimating the capacity of the organ.

**Bladder in the Newly-born Infant and in the Child.**—At birth the empty bladder is spindle- or torpedo-shaped, and its long axis, which extends from the point of attachment of the urachus to the internal urethral orifice, is directed downwards and backwards (Fig. 819). The lateral and posterior borders seen in the adult organ cannot be recognised at birth, nor is there any part of the bladder wall directed downwards and backwards, as is the basal surface of the adult organ. In the fœtus and young child the bladder occupies relatively a much higher level than it does in the adult, and, even when empty, it extends upwards into the abdominal cavity. Its anterior aspect is in contact with the posterior surface of the anterior abdominal wall. At birth the peritoneum forming the recto-vesical pouch covers the whole of the posterior surface of the bladder, and reaches as low as the upper limit of the prostate. The internal urethral orifice is placed at a high level, and sinks gradually after birth (Fig. 820, A). In the newly-born child this opening lies on a level with the upper margin of the symphysis pubis, and the openings of the ureters lie almost on a level with the plane of the pelvic brim. The obliterated hypogastric arteries are more intimately related to the bladder in the fœtus and child than in the adult, and lie close against its sides as they pass upwards towards the umbilicus (Fig. 821).

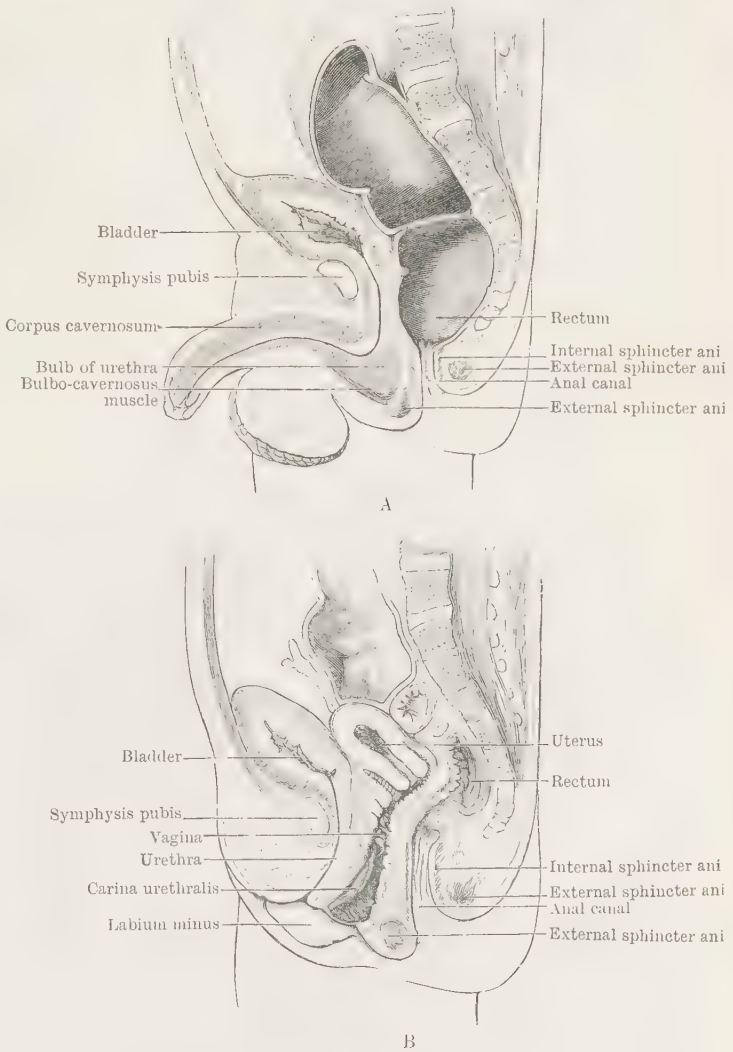

FIG. 820.—MESIAL SECTION THROUGH THE PELVIS OF NEWLY-BORN CHILD.
A, Male, and B, Female. From preparations in the Anatomical Department, Trinity College, Dublin.

**Peritoneal Relations and Connexions of the Bladder.**—We have already seen that the superior surface of the empty bladder is covered by peritoneum, which leaves it along the lateral border on each side to reach the pelvic wall at about the level of the white line (arcus tendineus) of the pelvic fascia. To this peritoneal

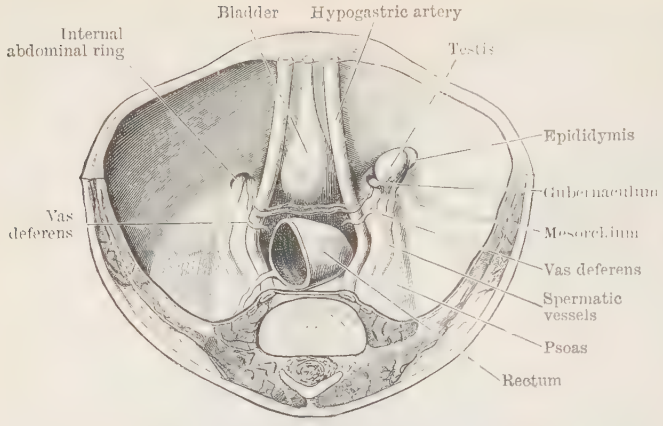

FIG. 821.—VIEW LOOKING FROM ABOVE INTO THE PELVIS AND LOWER PART OF THE ABDOMINAL CAVITY IN A FŒTUS OF ABOUT THE SEVENTH MONTH.

On the left side, which represents a slightly more advanced condition than the right, the testis has entered the inguinal canal; on the right side the testis is still within the abdominal cavity.

reflection the term **lateral false** (or peritoneal) **ligament** is often applied. The lateral ligaments of opposite sides are continuous in front at the bladder apex, in which position the peritoneum is conducted over the fibrous cord of the urachus to reach the anterior abdominal wall, forming the so-called **anterior false** (or peritoneal) **ligament.** When the bladder is empty the level of this anterior reflection lies just behind, or just below, the upper margin of the symphysis pubis. When the bladder becomes filled the level of the peritoneal reflection forming the anterior false liga-

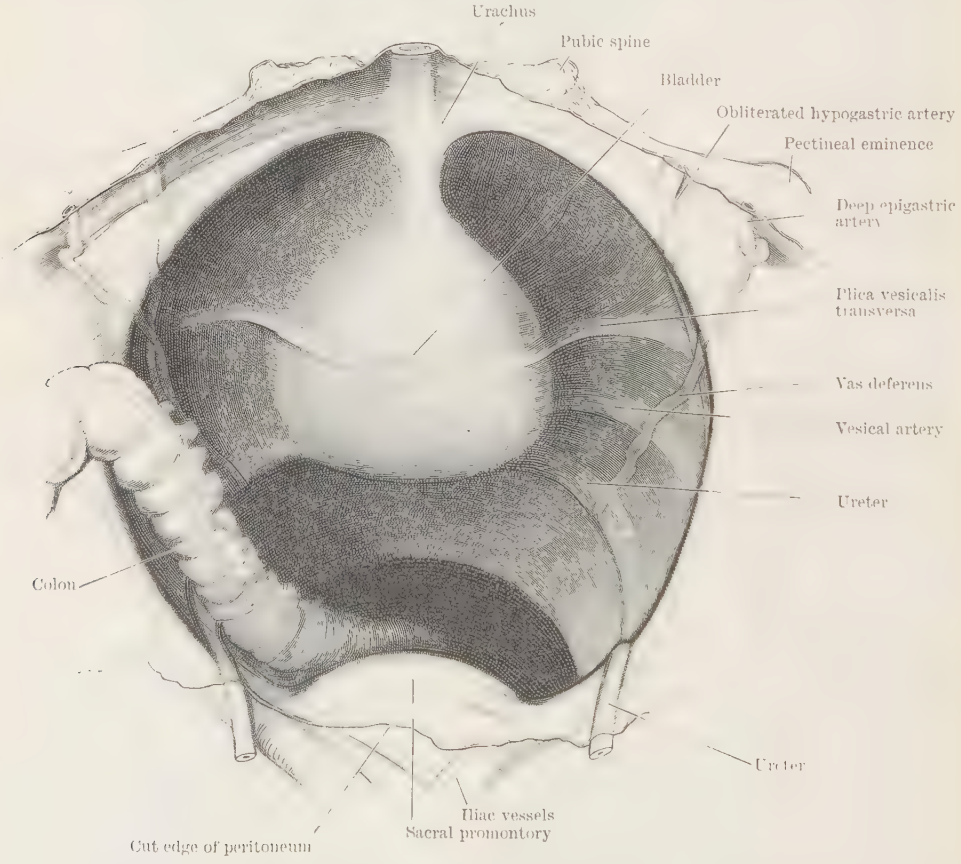

FIG. 822.—VIEW LOOKING INTO THE MALE PELVIS FROM ABOVE AND SOMEWHAT BEHIND.

From a specimen in which the bladder was firmly contracted and contained but a small amount of fluid. The paravesical fossa is seen on each side of the bladder. The deep peritoneal pouch in front of the rectum is bounded by marked crescentic folds (sacro-genital or posterior false ligaments of the bladder), which meet together some distance behind the posterior border of the bladder.

ment is raised upwards, and may reach a point two inches, or more, above the upper

margin of the symphysis pubis. Similarly, the line along which the lateral peritoneal ligament reaches the pelvic wall is also carried upwards in distension of the bladder, and may reach the level of the vas deferens and of the obliterated hypogastric artery.

When the bladder is empty the peritoneum is carried downwards upon the side wall of the pelvis as low as the lateral border of the organ, and lines a shallow depression which receives the name of **paravesical fossa**. This peritoneal fossa lies below the level of the so-called obturator fossa, from which it is separated by the vas deferens. As the bladder fills the peritoneum is raised off this part of the pelvic wall, and certain structures, such as the obturator vessels and nerve and the vas deferens, which lie on the side wall of the pelvis, come into direct relationship with the lateral aspect of the distended bladder.

Posteriorly the peritoneum leaves the upper surface of the empty bladder at its posterior border, and is carried backwards, forming a kind of horizontal shelf, or fold, for a distance of about half an inch, giving at the same time a partial covering to the vasa deferentia and upper ends of the seminal vesicles. The peritoneum then suddenly dips downwards to reach the bottom of the recto-genital (or recto-

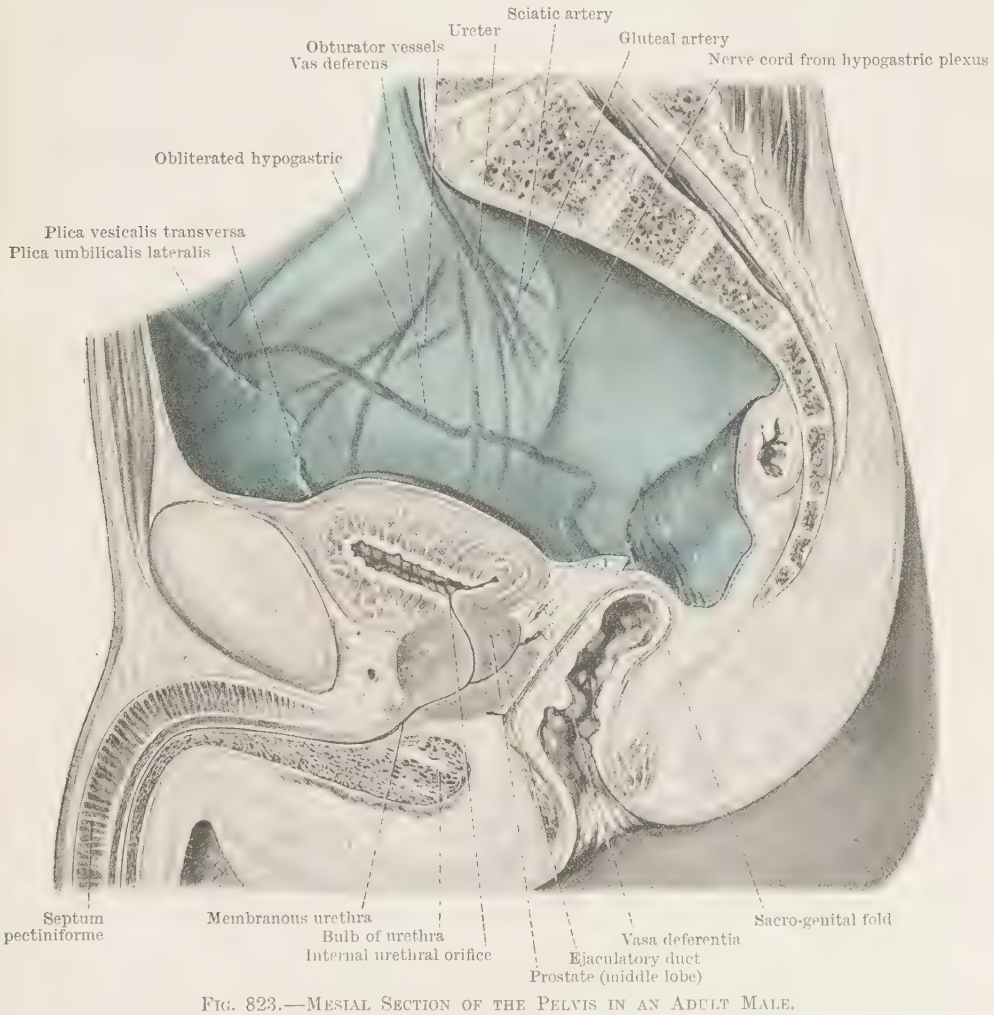

Fig. 823.—Mesial Section of the Pelvis in an Adult Male.

The coils of small intestine which lay within the pelvis have been lifted out in order to give a view of the side wall of the pelvic cavity. The peritoneum is coloured blue.

vesical) pouch, where it is reflected on to the anterior surface of the rectum (Fig. 823). As a rule, no part of the basal surface of the contracted and empty bladder receives a covering from the peritoneum, since the seminal vesicles

and terminal portions of the vasa deferentia intervene as they lie in the anterior wall of the recto-genital pouch. When the bladder is distended the posterior border, separating the upper and basal surfaces, is rounded out, and the peritoneum forming the horizontal shelf, just described, is taken up (compare Figs. 810 and 823). It is to be specially noted that the level of the peritoneal reflection, forming the bottom of the recto-genital pouch, does not alter to any considerable extent in distension of the bladder (Figs. 809 and 810).

An examination of mesial sections of the pelvis shows the great danger run by the ampullæ of the vasa deferentia in any operation for reaching the bladder through the anterior wall of the rectum, and the difficulty in avoiding injury to the peritoneum.

The term "**posterior false** (or peritoneal) **ligament**" is often applied to the somewhat variable crescentic fold of peritoneum which bounds on each side the entrance to the recto-genital pouch, and which often unites with the fold of the opposite side across the middle line, behind the posterior border of the bladder and the vasa deferentia. These folds represent the folds of Douglas in the female, and are to be regarded as connexions of the vasa deferentia rather than of the bladder, hence the term **sacro-genital folds** is applicable to these structures in both sexes. The folds are seen in Figs. 822 and 823.

**In the female** the peritoneum is reflected posteriorly from the upper surface of the bladder on to the anterior aspect of the uterus.

The peritoneum covering the upper surface of the empty, or partly distended, bladder often exhibits a transversely-disposed fold or wrinkle, to which the term **plica vesicalis transversa** has been applied. This fold, when well developed, can be traced on to the side wall of the pelvis, where it traverses the paravesical fossa, and in some cases it is found to cross the pelvic brim and to be directed towards the internal abdominal ring (Figs. 822 and 823).

**Fixation of the Bladder.**—When the fibrous cord of the **urachus** (ligamentum umbilicale medium), which binds the bladder apex to the anterior abdominal wall, and the peritoneal folds, already described as the false ligaments, are severed, the bladder is easily moved about, except in its lower and basal parts. Anteriorly it is connected to the pubis, and laterally to the fascial lining of the pelvis by loose areolar tissue only, which permits free movement during expansion and contraction. The lower fixed part of the bladder is chiefly held in place by processes of the pelvic fascia, continuous with those forming the capsule of the prostate. The fascial connexions constitute the true ligaments of the bladder, and are described as **pubo-prostatic** or **anterior ligaments**, reaching the bladder from the pubis in front, and **lateral ligaments**, reaching the bladder from the fascial lining of the side wall of the pelvis.

In addition to the urachus and the peritoneal and true ligaments already mentioned, the bladder is supported and fixed in position, in the region of its basal surface, by the dense fibrous and unstriped muscular tissue which surrounds the seminal vesicles, the terminal portions of the vasa deferentia and the ureters.

Laterally the strands of connective tissue and the bundles of muscle fibres forming this support pass backwards to gain attachment to the fascia in connexion with the rectum, and the front of the sacrum. Muscle fibres connected with the bladder wall are also found within the pubo-prostatic ligaments, through which they are attached to the pubis.

*In the female* the basal part of the bladder wall is supported and held in place by its connexion with the anterior wall of the vagina. The region of the urethral orifice is the most firmly fixed part of the bladder wall in both sexes.

**Structure of the Bladder Wall.**—The wall of the bladder from without inwards is composed of a serous, a muscular, a submucous, and a mucous coat. The **serous coat** (tunica serosa), formed by peritoneum, is incomplete, and covers only the upper and posterior parts of the distended bladder (Fig. 814).

A considerable amount of fibrous connective tissue surrounds the **muscular coat**, and penetrating it divides it into numerous coarse bundles of muscle fibres. All the muscle fibres are of the smooth variety, and the bundles formed by them are arranged in three very imperfectly separated strata called external, middle, and internal. The **external**

**stratum** (stratum externum) is for the most part made up of fibres which are directed longitudinally, and it is best marked near the middle line on the upper and under aspects of the bladder. Farther from the middle line, on the sides of the bladder, the fibres composing the external stratum run more obliquely, and their directions frequently cross one another. In the male, many of the fibres of the external stratum are attached both anteriorly and posteriorly to the prostate, and in the female the corresponding fibres join the dense tissue which in this sex surrounds the upper part of the urethra. Other fibres of this stratum on each side of the body join the lower part of the symphysis pubis and constitute the **musculus pubo-vesicalis**, which lies in the substance of pubo-prostatic ligament. Lastly some fibres of the external stratum blend posteriorly with the anterior aspect of the rectum and receive the name of **musculus recto-vesicalis**. The **middle stratum** (stratum medium) is composed of fibres which for the most part run circularly, and forms the greater part of the thickness of the muscular coat. In the region of, and behind, the urethral orifice the bundles of fibres are finer and more densely arranged and surround the opening in a plane which is directed obliquely downwards and forwards. This part of the middle stratum is often spoken of as the **sphincter vesicæ**. Inferiorly the fibres of the sphincter vesicæ are continuous with the muscular tissue of the prostate in the male, and with the muscular wall of the urethra in the female. In other parts of the bladder the fibres of the middle stratum are coarser and separated by intervals filled by connective tissue. The **inner stratum** (stratum internum) is a thin layer of fibres directed for the most part longitudinally.

The **submucous coat** (tela submucosa) is composed of areolar tissue, but contains numerous fine elastic fibres.

The **mucous coat** (tunica mucosa) is loosely attached, by means of the submucous layer, to the subjacent muscular coat, except in the region of the trigonum vesicæ, where the muscular fibres lie close beneath, and are firmly adherent to the mucous membrane. Over the trigonum the mucous coat is always smooth and flat; elsewhere it is thrown into folds when the bladder is empty. The mucous membrane of the bladder is continuous with that of the ureters and urethra. The epithelium, covering it, varies much in appearance in different conditions of the organ, and is of the variety known as transitional stratified epithelium.

**Vessels and Nerves of the Bladder.**—The bladder receives its blood supply on each side from the **superior** and **inferior vesical arteries**. The superior vesical artery arises from the pervious part of the hypogastric artery, and the inferior vesical from the internal iliac. The largest veins are found just above the prostate, and in the region where the ureter reaches the bladder. They form a dense plexus which pours its blood into tributaries of the internal iliac vein, and communicates below with the prostatic plexus. The **lymphatics** from the bladder join the iliac group of glands.

The nerve supply of the bladder is derived on each side from the **vesical plexus**, the fibres of which come from two sources, namely (1) from the **upper lumbar nerves** through the hypogastric plexus, and (2) from the **third** and **fourth sacral nerves**. The fibres from the latter sources join the vesical plexus directly.

## THE URETHRA.

The **urethra** is the channel which serves to convey the urine from the bladder to the exterior. In the *male* it consists of two portions, a proximal part, less than one inch in length, extending from the bladder to the points where the ducts of the reproductive glands join the canal, and a much longer distal portion which serves as a common passage for the secretion of the kidneys and for the generative products. An account of the male urethra follows the description of the male reproductive glands and passages (see p. 1177). In the *female* the urethra is more simple in its arrangement, and represents only the proximal part of the male canal. It is a short passage leading from the bladder to the external urethral orifice—an aperture placed within the urinogenital cleft immediately above and in front of the opening of the vagina.

**Female Urethra.**—The female urethra (urethra muliebris) is a canal of about one to one and a half inches in length, which follows a slightly curved direction downwards and forwards, below and behind the lower border of the symphysis pubis. As it leaves the pelvis the urethra pierces the triangular ligament, and the part of the passage which lies between the deep and superficial layers of this ligament is surrounded by the fibres of the compressor urethræ muscle. Except

during the passage of fluid the canal is closed by the apposition of its anterior and posterior walls. The **external orifice** (orificium urethræ externum) is placed between the labia minora, immediately in front of the opening of the vagina, and lies about one inch below and behind the clitoris (Fig. 855). The opening is slit-like, and is bounded by slightly marked lateral lips. The posterior wall of the urethra, except

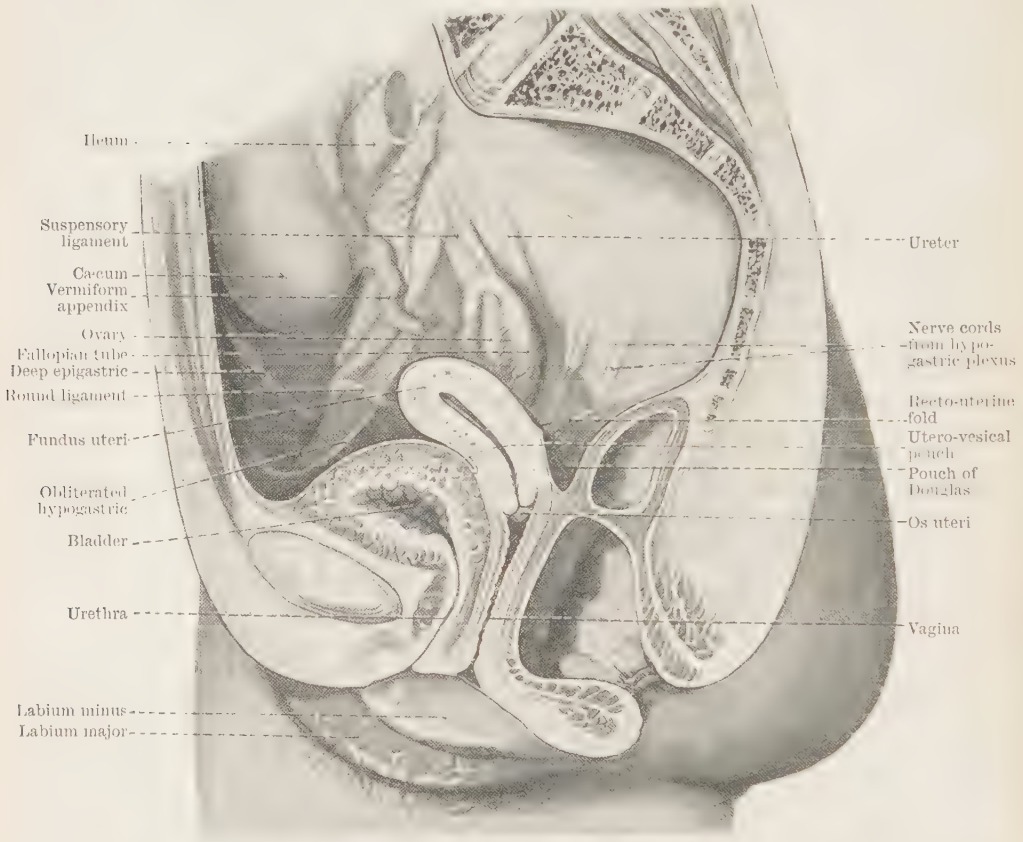

Fig. 824.—Mesial Section through the Female Pelvis. Drawn for the most part from a model of a dissection by Dr. E. H. Taylor.

in its upper part, is very intimately connected with the anterior wall of the vagina. The mucous lining of the canal is raised into a number of slightly marked longitudinal folds, one of which, more distinct than the others, and placed upon the posterior wall of the passage, receives the name of **crista urethralis**.

**Structure.**—The wall of the female urethra is thick and contains much fibrous tissue, especially in its outer part, and this passes without any sharp line of demarkation into the surrounding mass of connective tissue. The muscular coat of the urethra (tunica muscularis) is continuous above with that of the bladder, and is composed of layers of circularly and longitudinally disposed smooth muscle fibres arranged to form outer and inner strata. Within the muscular coat the wall of the urethra is very vascular, and the canal itself is lined by a pale mucous membrane which is thrown into longitudinally-directed folds, one of which is the crista urethralis mentioned above. The epithelium of the canal, in its upper part, is of the transitional variety, like that of the bladder; in its lower part it becomes scaly. Numerous minute glands (glandulæ urethrales) and pit-like depressions (lacunæ urethrales) open into the urethral canal. One group of these glands possesses a minute common duct (ductus paraurethralis), which opens into the urinogenital cleft by the side of the urethral orifice. It is believed that these latter glands represent the prostatic glands of the male subject. The vascular layer which lies between the muscular coat and the mucous membrane contains elastic fibres, and in appearance resembles erectile tissue. Striped muscle fibres are present on the outer

aspect of the muscular coat of the urethra. In the upper part of the canal these fibres form a complete ring-like sphincter, but in the middle and lower parts the striped muscle fibres though present in front are absent in the posterior wall of the urethra, as at this level they pass backwards on the outer aspect of the vagina, and enclose this latter passage together with the urethra in a single loop of muscle tissue. The lower fibres, therefore, form a urinogenital sphincter.

## THE MALE REPRODUCTIVE ORGANS.

We have here to describe (1) the testes or essential reproductive glands of the male, together with their (2) coverings and (3) ducts, (4) the prostate, (5) Cowper's glands, (6) the external genital organs, and (7) the male urethra.

The reproductive glands of the male, or **testes**, are a pair of nearly symmetrical oval-shaped bodies situated in the scrotum. The duct of each gland, at first much twisted and intertwined, forms a structure known as the **epididymis**, which is applied against the posterior and outer part of the testis. From the epididymis the excretory duct, or **vas deferens**, passes upwards towards the lower part of the anterior abdominal wall, which it pierces very obliquely, to enter the abdominal cavity. Here each vas deferens is covered by the peritoneum, and almost at once crossing the pelvic brim, enters the pelvis. The vas now runs on the side wall of the pelvis towards the base of the bladder, where it comes into relation with a branched tubular structure termed the **vesicula seminalis**. Joined by the duct of the vesicula seminalis, the vas deferens forms a short canal called the **common ejaculatory duct**, which terminates by opening into the prostatic part of the **urethra**. The **prostate**, a partly glandular, partly muscular structure, surrounding the first part of the urethra, and also a pair of small glandular bodies called **Cowper's glands**, are accessory organs connected with the male reproductive system. The ducts of Cowper's glands and those of the prostate, like the common ejaculatory ducts, open into the urethra, which thus serves not only as a passage for urine, but also for the generative products. The external genitals are the **penis** and **scrotum**.

### THE TESTIS.

The male reproductive glands, the testicles or **testes**, are a pair of somewhat oval, slightly flattened bodies of a whitish colour, measuring about an inch and a half in length, one inch from before backwards, and rather less in thickness. Each testis is placed within the cavity of the scrotum in such a manner that its long axis is directed upwards, slightly forwards, and outwards, and usually the left gland occupies a lower level than the right. The testis (Fig. 825) has two somewhat flattened surfaces, one of which, called the *outer surface* (facies lateralis) looks outwards and backwards; the other, or *inner surface* (facies medialis), looks inwards and forwards, and is usually the more flattened. The two surfaces are separated by two rounded borders, of which the *anterior* (margo anterior) is the more convex, and is free, while the *posterior* (margo posterior) is less rounded, and is the one by which the organ is suspended within the scrotum. A structure called the **epididymis**

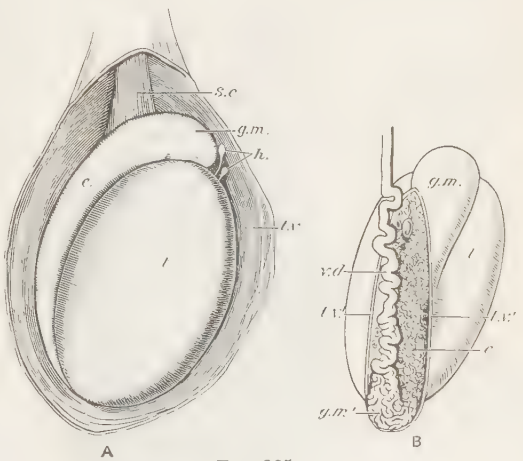

Fig. 825.

and the lowest portion of the **spermatic cord** are attached to the posterior border of the testis. Each border ends above in the *upper*, and below in the *lower extremity* of the testis (extremitas superior et extremitas inferior). Owing to the obliquity of the long axis of the gland, the upper extremity of the testis lies on an anterior and external plane to the lower one.

**Epididymis.**—The epididymis is a somewhat crescentic structure, which is curved round the posterior border of the testis and overlaps to some extent the posterior part of the outer surface of that organ. The upper, somewhat swollen part of the epididymis, is called the **globus major** (caput epididymidis), and overhangs the upper end of the testis, to which it is directly connected by numerous emerging ducts, by connective tissue, and by the serous covering of the organ. The lower and smaller end is termed **globus minor** (cauda epididymidis), and is attached by loose areolar tissue and by the serous covering to the lower end of the testis. The intermediate part, or **body** (corpus epididymidis), is applied against, but is separated from, the posterior part of the outer surface of the testis by an involution of the serous covering of the organ, which forms an intervening pocket termed the digital fossa (sinus epididymidis).

The main mass of the epididymis is composed of an irregularly twisted canal, the canal of epididymis, which forms the first part of the duct of the testis.

Minute sessile, or pedunculated, bodies are often found attached to the globus major or to the upper end of the testis. These are called appendices of the epididymis and testis (appendices testis), or hydatids of Morgagni, and have a developmental interest. The minute body which lies on the upper end of the testis represents the free end of Müller's duct in the embryo and the fimbriated end of the Fallopian tube of the female; it is usually sessile. Above the globus major, and in front of the lower part of the spermatic cord, there may also be present a small rudimentary body called the **organ of Giraldes** or **paradidymis**. This is rarely seen in the adult and is best marked in young children.

**Tunica Vaginalis.**—The cavity within which the testis and epididymis are placed is lined by a smooth serous membrane—the tunica vaginalis—which resembles in appearance and structure the peritoneum from which it is originally derived. The cavity is considerably larger than the contained structures, and extends not only down to a lower level than the testis, but also reaches upwards to a higher level than the gland. The sac, or cavity, tapers as it is traced upwards, and above the level of the testis the spermatic cord bulges forwards into its posterior part. The tunica vaginalis lines the cavity for the testis, and is reflected from the posterior wall of the scrotal chamber over the testis and epididymis, giving a covering to each. The part of the membrane lining the cavity is called the **parietal portion** (lamina parietalis) of the tunica vaginalis, while the part clothing the testis and epididymis is termed the **visceral portion** (lamina visceralis). Between the outer surface of the testis and the body of the epididymis, the visceral part of the tunica vaginalis dips in and lines a narrow interval called the **digital fossa** (sinus epididymidis). The entrance to the fossa is limited above and below by short crescentic folds of the tunica vaginalis, which pass from the testis to the globus major and minor of the epididymis. These folds are spoken of as the superior and inferior ligaments of the epididymis. In three positions the surface of the testis receives no covering from the tunica vaginalis,—superiorly where the globus

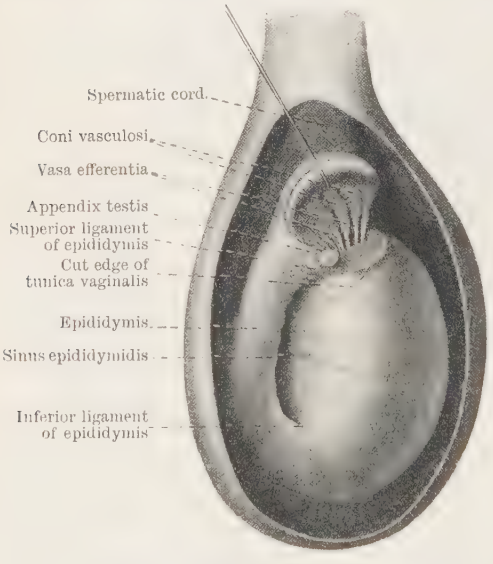

FIG. 826.—RIGHT TESTIS WITHIN TUNICA VAGINALIS. In the region of the globus major the tunica vaginalis has been cut through and the globus major of the epididymis has been raised to show the vasa efferentia and coni vasculosi.

major is attached, inferiorly where the globus minor is in contact, and posteriorly where the blood-vessels and nerves enter the organ from the spermatic cord.

**Structure of the Testis and Epididymis.**—Beneath the serous tunica vaginalis the testis is invested by an external coat, composed of dense white inelastic fibrous tissue called the **tunica albuginea**, from the deep surface of which a number of slender fibrous bands or septa dip into the gland. These—the **septula testis**—imperfectly divide the organ into a number of wedge-shaped parts called **lobes**, or **lobules** (lobuli testis, Fig. 825). All the septa end posteriorly in a mass of fibrous tissue which is directly continuous with the tunica albuginea, and which projects forwards into the testis along its posterior border. This structure receives the name of **mediastinum testis**, or **corpus Highmori**, and is traversed by an exceedingly complicated network of fine canals, into which the minute tubules which compose the substance proper of the testis open. The mediastinum is also pierced by the arteries, veins, and lymphatics of the testis. These vessels enter the posterior border of the organ, and traversing the mediastinum, spread out on the fibrous septa which radiate towards all parts of the deep surface of the tunica albuginea. In this way a delicate network of vessels (tunica vasculosa) is formed on the deep surface of the tunica albuginea and on the sides of the septa.

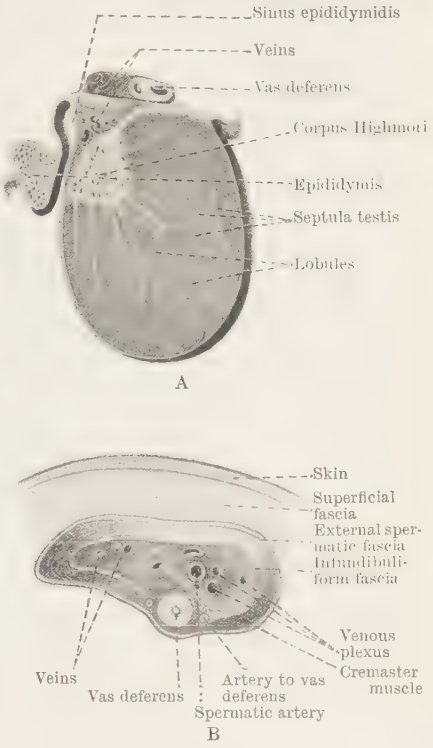

Fig. 827.

A. Transverse section of testis and epididymis.
B. Transverse section of spermatic cord below external abdominal ring.

The mediastinum, the septa, and the tunica albuginea form a framework enclosing a number of imperfectly isolated spaces which are filled by a loosely packed substance of a light-brown colour called the **parenchyma of the testis** (parenchyma testis).

The parenchyma is composed of enormous numbers of much-convoluted **seminiferous tubules** (tubuli seminiferi contorti), and completely fills up the intervals between the septa. The minute tubules look like fine threads to the unaided eye, and are but loosely held together by a small amount of connective tissue. Usually three or four tubules are found in each lobule of the gland, and the total number in the testis has been estimated at about 600. The seminiferous tubules, after a course of about two feet in length, pass towards the mediastinum testis, and unite, at acute angles, to form a smaller number of slender tubes which run a straight course. These latter are called **tubuli recti**, and open into a complicated network of fine canals situated in the substance of the mediastinum, called the **rete testis.** The tubules are much more twisted and convoluted in the cortical part of the gland, near the tunica vaginalis, than in the region of the mediastinum, and often in this position give off side branches which, according to some observers, may effect anastomoses between the tubules. It appears doubtful, however, if the tubules of the **testis** do really anastomose.

Microscopic sections show that the walls of the seminiferous tubules are composed of a basement membrane and of an epithelial lining, formed of several layers of cells. Certain cells of this epithelium are, in the adult, constantly undergoing transformation into **spermatozoa**, and the appearance of the tubules in section varies much, according to age and to the greater or less activity of the epithelial cells.

The secretion of the seminiferous tubules is carried through the tubuli recti into the rete testis, and leaves the latter, to reach the canal of the epididymis,

through from fifteen to twenty minute tubules called **vasa efferentia** (ductuli efferentes testis). These latter pierce the tunica albuginea and enter the globus major, where it is in direct contact with the upper end of the testis. Each vas efferens is at first straight, but soon becomes much convoluted, and forms a little conical mass of twisted tubule called a **conus vasculosus** (lobulus epididymidis). Within the globus major the little canals finally open into the single much-convoluted tube which constitutes the chief bulk of the epididymis, and is called the **canal of the epididymis** (ductus epididymidis). This canal, which is not less than 19 or 20 feet in length, may be said to begin in the globus major, and to end, after an extraordinarily tortuous course, at the globus minor by becoming the vas deferens (ductus deferens, Fig. 828).

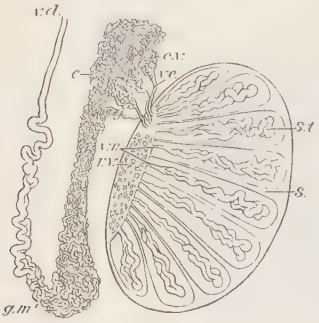

FIG. 828.

DIAGRAM to illustrate the structure of the testis and epididymis.

| *r.v.* | Rete testis. | *v.e.* | Vas efferens. |
| *s.* | Septula testis. | *v.r.* | Tubuli recti. |

In most cases one or more slender convoluted diverticula from the canal of the epididymis may be found near its lower end. These receive the name of **vasa aberrantia** (ductuli aberrantes), and one of them which is very constantly present often measures a foot or more in length.

**Minute Structure.**—The canal of the epididymis and the vasa efferentia are lined by a ciliated epithelium, the cilia of which maintain a constant current towards the vas deferens. The canal of the epididymis possesses a muscular coat composed of an inner stratum of transversely and an outer stratum of longitudinally directed fibres. The wall, at first thin, becomes much thicker as the canal approaches the vas deferens.

**Vessels and Nerves of the Testis.**—The testis is supplied by the **spermatic artery**, a branch of the aorta. This slender vessel, after a long course, reaches the posterior border of the testis, where it breaks up into branches which enter the mediastinum testis, and are distributed along the septa and on the deep surface of the tunica albuginea. The **veins** issuing from the posterior border of the testis form a dense plexus, called the **plexus pampiniformis**, which finally pours its blood through the spermatic vein, on the right side, into the inferior vena cava; on the left side the spermatic vein joins the left renal vein. The **nerves** for the testis accompany the spermatic artery, and are derived through the **aortic** and **renal plexuses** from the tenth thoracic segment of the spinal cord. The afferent fibres from the epididymis appear to reach the spinal cord through the posterior roots of the eleventh and twelfth thoracic and first lumbar nerves. The arteries and nerves of the testis communicate with those on the lower part of the vas deferens, namely, with the artery of the vas and with twigs from the hypogastric plexus. The **lymphatic vessels** of the testis pass upwards in the spermatic cord, and end in the lumbar lymphatic glands.

## THE VAS DEFERENS.

The **vas deferens** (ductus deferens) is the direct continuation of the canal of the epididymis. Beginning at the lower extremity of the epididymis, it ends, after a course of nearly 18 inches, by opening as the **common ejaculatory duct** into the prostatic or first part of the urethra. The duct in parts of its course is somewhat convoluted, and the actual distance traversed by it is not more than 12 inches. Placed in the first instance outside the abdominal cavity, the vas deferens ascends within the scrotum towards the lower part of the anterior abdominal wall, which it reaches not far from the middle line. During this part of its course the duct, together with the vessels and nerves of the testis, is surrounded by a number of loose coverings derived from certain layers of the abdominal wall, and the cord-like structure so formed is termed the **spermatic cord**. The vas deferens, together with the accompanying vessels and nerves, now passes through the abdominal wall in an oblique passage, to which the name **inguinal canal** is applied. Within the abdomen the vas lies immediately beneath the peritoneum, and soon crossing over the pelvic brim, it enters the pelvis, on the side wall of which it proceeds backwards towards the base of the bladder. Here, near the middle line, the vas deferens is joined by the duct of the corresponding **vesicula seminalis**, and the common ejaculatory duct, thus formed, having traversed the prostate, opens into the urethra.

At first the vas deferens, like the canal from which it takes its origin, is very

tortuous, but soon increasing in thickness, the duct becomes less twisted, and passes upwards along the inner side of the epididymis, behind the testis, to enter the spermatic cord (Fig. 828). Its course is now almost vertically upwards towards the spine of the pubis, near which, crossing the inner part of Poupart's ligament, the vas enters the inguinal canal by the external abdominal ring. Of the structures composing the spermatic cord the vas is the most posterior, and it can be readily

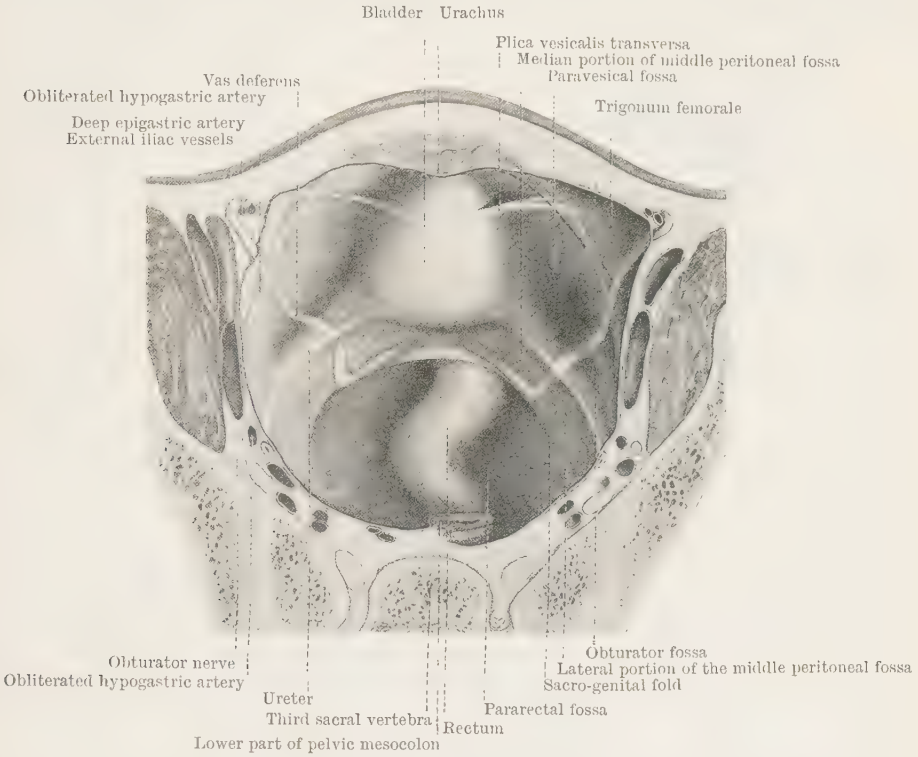

Fig. 829.—The Peritoneum of the Pelvic Cavity. The upper part of the posterior wall of the pelvis has been removed to show more clearly the disposition of the peritoneum. (Birmingham.)

distinguished, even in the undissected subject, by its hard firm feel when it is taken between the finger and thumb. In the inguinal canal the vas is directed outwards, upwards, and a little backwards to the internal abdominal ring, where, at a point half an inch above Poupart's ligament, and midway between the symphysis pubis and the anterior superior iliac spine, it enters the abdomen. The distance between the point where the cord enters the inguinal canal to the point where it leaves it to enter the abdomen is about one and a half inches. While passing from the external to the internal abdominal ring the vas deferens, together with the other structures of the spermatic cord, rests upon the upper grooved surface of Poupart's ligament, and is placed behind the aponeurosis of the external oblique and some of the lower fibres of the internal oblique muscle. From before backwards the vas rests, in the first instance, upon the conjoined tendon of the internal oblique and transversalis muscles, and farther outwards upon the transversalis fascia. Above the cord are some arching fibres of the internal oblique muscle, which enter the conjoined tendon. As the vas deferens leaves the inguinal canal by the internal abdominal ring, it turns round the deep epigastric artery on its outer and posterior aspect. Completely changing the direction of its course, the duct now runs for a short distance backwards, inwards, and upwards, beneath the peritoneum to a point one and a half to two inches from the spine of the pubis, where it crosses the ilio-pectineal line and enters the pelvis. In this part of its course the duct usually at first lies in front of the external iliac vessels, and then in the floor of a little triangular fossa

(trigonum femorale) between these vessels and the pelvic brim. On the side wall of the pelvis the vas is continued backwards, and a little downwards and inwards, in the direction of the ischial spine, and lies immediately beneath the peritoneum, through which it can usually be seen shining. In the pelvic part of its course the vas deferens crosses on the inner side of (1) the obliterated hypogastric artery, (2) the obturator nerve and vessels, (3) the vesical vessels, and (4) the ureter (Fig. 823).

Beyond the ureter the vas takes a somewhat sudden bend, and passes downwards and inwards towards the middle line, beneath the peritoneum of the pelvic floor. Reaching the interval between the base of the bladder in front and the rectum behind, the vasa deferentia of opposite sides occupy the angle formed between the vesiculæ seminales (Fig. 831). As they approach one another each vas becomes somewhat tortuous, sacculated, and dilated, and assumes a general resemblance in structure to a portion of the vesicula seminalis. This dilated part of the vas deferens is termed the **ampulla** (ampulla ductus deferentis). As it turns inwards the vas lies a short distance behind the ureter, and immediately in front of the free edge of the peritoneal fold (sacro-genital) which bounds the recto-genital pouch of the peritoneum. Just above the base of the prostate the vas deferens becomes once more a narrow canal, and in this position it is joined by the duct of the corresponding seminal vesicle to form the **common ejaculatory duct**, which, after a short course downwards, forwards, and inwards through the prostate, opens into the urethra.

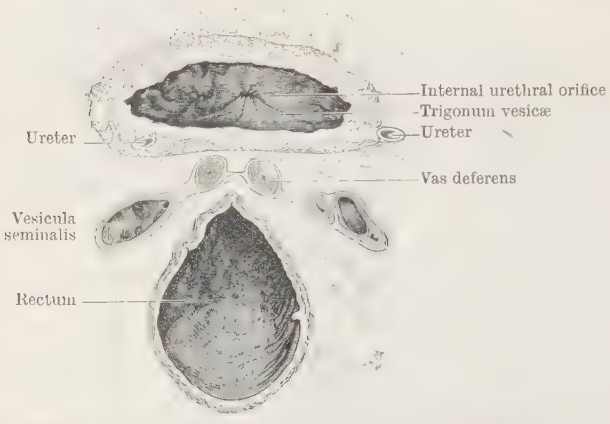

Fig. 830. - Horizontal Section through the Rectum and Bladder at the Level at which the Ureters pierce the Bladder Wall.

From a specimen in the Surgical Museum, Trinity College, Dublin.

In some cases the vas deferens crosses the obliterated hypogastric artery before it enters the pelvic cavity; it normally does so in the fœtus.

**Common Ejaculatory Duct** (ductus ejaculatorius).—This minute duct, formed by the union of the vas deferens with the duct of the corresponding seminal vesicle, is less than one inch in length, and lies very close to its fellow of the opposite side as it passes through the prostate behind its mesial lobe. The ducts open by slit-like apertures into the first part of the urethra, one on each side of the **sinus pocularis** (utriculus prostaticus).

The mucous membrane of the duct is thrown into numerous complicated folds, and in connexion with it are a number of remarkable minute diverticula which are enclosed within the muscular coat of the duct.

**Seminal Vesicles.**—The vesiculæ seminales, or seminal vesicles, are a pair of hollow sacculated structures placed in front of the rectum and behind the bladder (Fig. 831). Each vesicula seminalis is usually about two inches in length, and has its long axis directed downwards, inwards, and somewhat forwards. The upper extremity of the vesicle, which is partly covered by peritoneum, is large and rounded, and lies at a considerable distance from the middle line, behind the lower end of the ureter. The peritoneum of the recto-genital pouch separates the upper end of the seminal vesicle from the rectum; below the peritoneal cavity the vesicle and rectum are more intimately related. The vesicle tapers towards its lower end, which is placed close to the middle line and immediately above the prostate. Inferiorly, the vesicle becomes constricted to form a short duct (ductus excretorius), which joins the outer side of the corresponding vas deferens at an acute angle to

form the common ejaculatory duct. The inner side of each vesicle is related to the vas deferens, and the outer side, when the bladder is empty, lies close to the sloping pelvic floor. The seminal vesicle often assumes a more vertical position when the bladder is distended, a more horizontal one when the bladder is empty. Its upper end is sometimes found to be curved backwards against the side of the rectum. The seminal vesicles are in some cases much smaller than usual, and may be less than one inch in length. Frequently they are unsymmetrical as regards size and shape. The seminal vesicles are more intimately related to the wall of

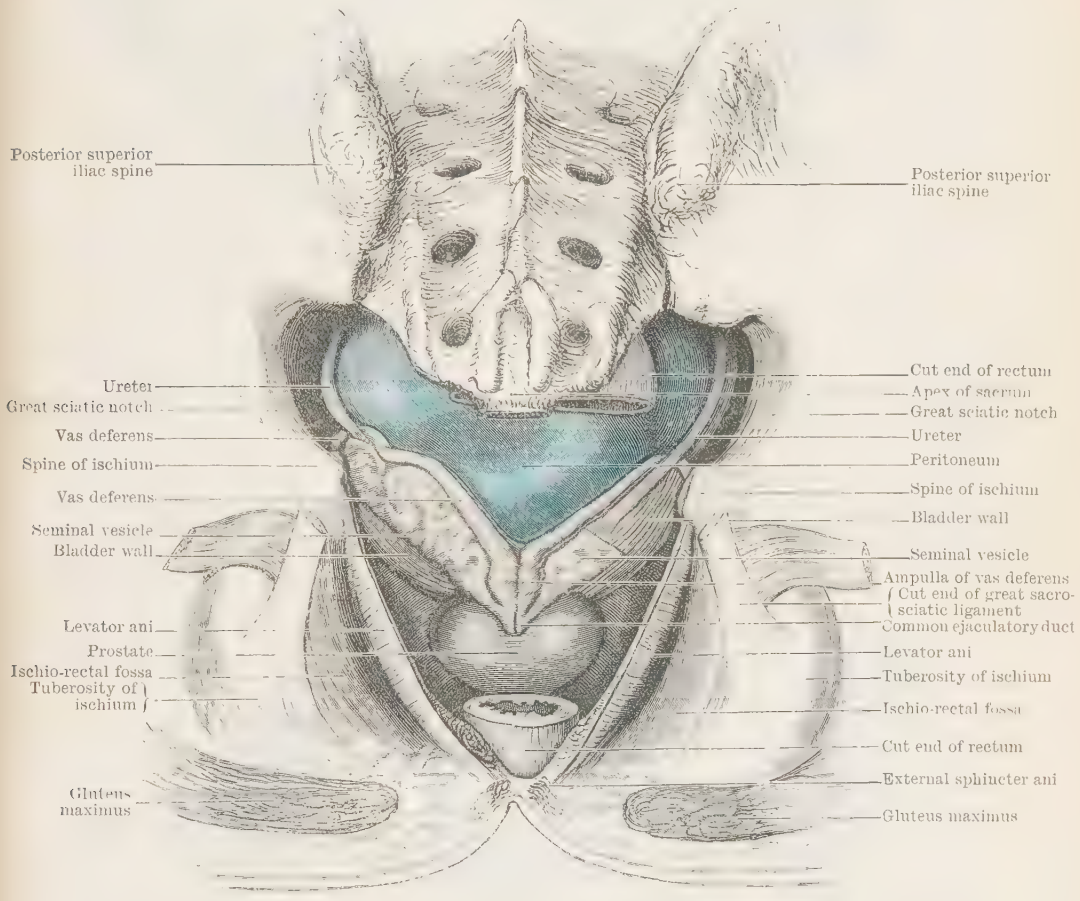

FIG. 831.—VIEW OF THE BASE OF THE BLADDER, PROSTATE, SEMINAL VESICLES, AND VASA DEFERENTIA FROM BEHIND.

The coccyx and the sacro-sciatic ligaments, together with the muscles attached to them, have been removed. The levatores ani have been separated along the median raphe, and drawn outwards. A considerable portion of the rectum and the upper part of the right seminal vesicle have been taken away. The peritoneum is coloured blue.

the bladder than to that of the rectum—their upper ends are, as we have seen, separated from the rectum by a portion of the recto-genital pouch of peritoneum, and lower down the septum of fascia which intervenes between the vesiculæ seminales and the rectum is denser than that which separates them from the bladder.

The vesicula seminalis is in reality a tube bent in a tortuous manner on itself, and if the dense connective tissue which envelops it be taken away, the length of the tube when untwisted may be found to be as much as five inches. The tube is closed above, and a variable number of short tortuous branches come off it at different levels. The blind end of the tube usually lies at the upper and outer extremity of the seminal vesicle, but in some cases the tubular vesicle is so bent

upon itself that the blind terminal part lies against the side of the issuing duct. The development of the vesiculæ seminales shows that they are to be looked upon as diverticula of the vasa deferentia, from which they originally arise as small pouches.

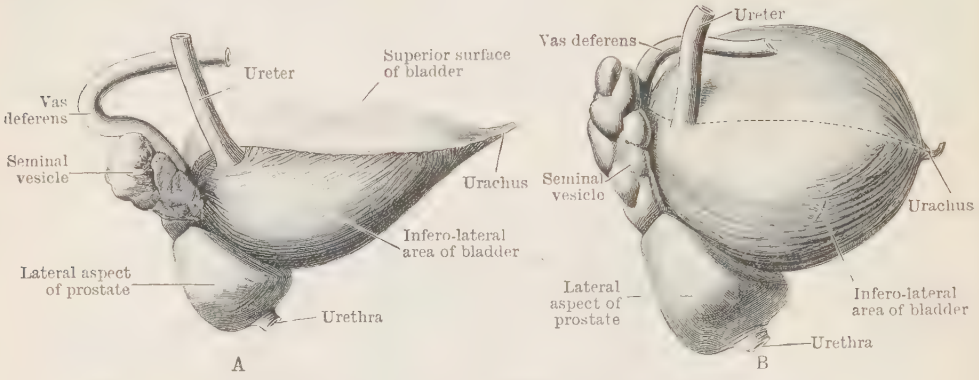

Fig. 832.—The Bladder, Prostate, and Seminal Vesicle viewed from the Side. Drawn from specimens hardened *in situ*.

In A the bladder contained but a small amount of fluid ; in B the quantity was somewhat greater.

The dense tissue in which the seminal vesicles are embedded contains much unstriped muscle tissue, which, sweeping round in the side wall of the recto-genital pouch, gains an attachment to the fascia in front of the sacrum and to the rectum. Inferiorly this tissue is attached to the capsule of the prostate. The large veins coming from the prostatic and vesical plexuses are closely related to the seminal vesicles.

**Structure of the Vas Deferens and of the Vesicula Seminalis.**—Except near its termination, where it is dilated to form the ampulla, the vas deferens is a thick-walled tube with relatively a very small lumen. The hard cord-like sensation which

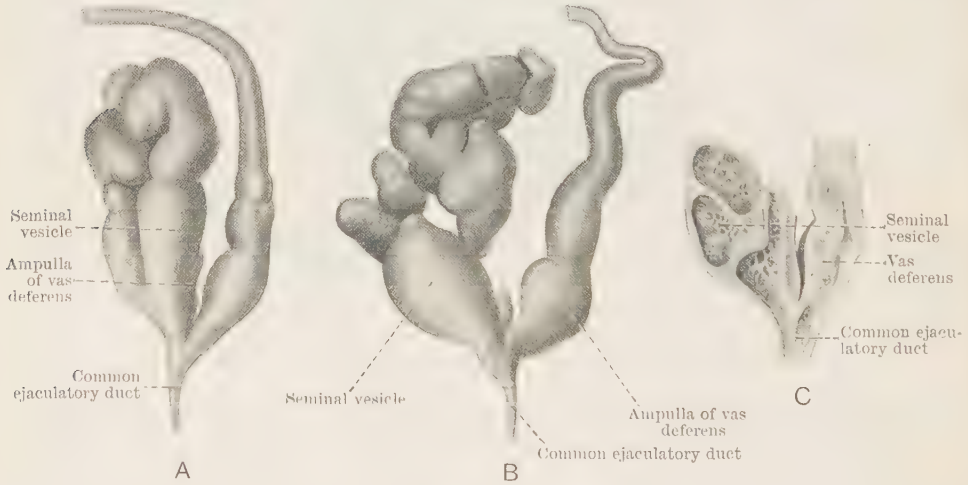

Fig. 833.

C. The seminal vesicle and vas deferens have been cut into to show the pitted structure of their walls.

the vas deferens conveys to the touch is due to the thickness and toughness of its wall, which is composed of three layers—an outer **fibrous** (tunica adventitia), an intermediate **muscular** (tunica muscularis), and an inner **mucous coat** (tunica mucosa). The thickness of the wall is due to the great development of the middle or muscular coat, which is composed of an intermediate layer of circularly and an inner and outer layer of longitudinally directed unstriped muscular fibres. Of these layers the middle one is by far the thickest and forms the chief part of the

thickness of the wall of the vas deferens. The mucous membrane of the vas exhibits a number of slight longitudinal folds and possesses a ciliated epithelium. The ampulla, or terminal part, possesses a much thinner wall, and, as the surface of its mucous membrane has a number of ridges separating depressed areas, the lining of this part of the tube presents a pitted or honeycombed appearance. The wall of the vesicula seminalis resembles that of the ampulla in being thin, and in having a mucous lining with uneven honeycomb-like ridges and depressions. In it the same coats are to be recognised as in the vas, but the muscular layer is much thinner, and the strata composing it less regularly arranged.

The seminal vesicles are not present in all mammals, and in those in which they do occur their relative size and form vary much. Among the carnivora, marsupials, and some other groups of mammals, the seminal vesicles do not occur; in some other animals, such, for instance, as the hedgehog, they are relatively of enormous size.

**Vessels and Nerves of the Vas Deferens and of the Vesicula Seminalis.**—The vas receives its arterial supply from the superior or inferior **vesical artery**. The **artery to the vas** accompanies that structure, supplying it as far as the testis, where it ends by anastomosing with branches of the spermatic artery. The vesicula seminalis is supplied by the **inferior vesical artery**. The nerves of the vas and vesicula seminalis are derived from the hypogastric plexus. In lower animals the nerves for the seminal vesicles leave the spinal cord by the nerve roots of the second, third, and fourth lumbar nerves.

## Descent of the Testis.

The peculiar course pursued by the vas deferens in the adult, and the manner in which it is related to the anterior abdominal wall, are rendered clear by a study of the arrangement of the parts that obtains in the fœtus. The testes until nearly the end of intra-uterine life are placed in the abdominal cavity. Lying at first on the posterior wall of the abdomen at the level of the two upper lumbar vertebræ, and just below the level assumed by the permanent kidney, the testis is held in place by a fold of peritoneum or mesentery, called the **mesorchium**. As growth goes on the testis is found to occupy a lower level in the abdominal cavity; in the third month it lies in the iliac fossa, and in the seventh it is situated near the internal abdominal ring. Meanwhile a blind pouch or diverticulum of the peritoneal membrane, termed the **processus vaginalis**, has grown downwards and inwards through the anterior abdominal wall towards the scrotum, deriving as it goes a covering from each of the layers of the abdominal wall through which it passes. The testis with its mesorchium enters the diverticulum of the abdominal cavity, and descends within it until the scrotum is reached. At a later stage, the connexion between the part of the processus vaginalis that lies in the scrotum and the peritoneal lining of the abdomen becomes lost by the obliteration of the upper part of the pouch. Thus the part of the processus vaginalis that persists in the scrotum becomes the parietal portion of the tunica vaginalis; while the visceral part of that membrane is the primitive peritoneal covering of the testis and epididymis (Figs. 834 and 835).

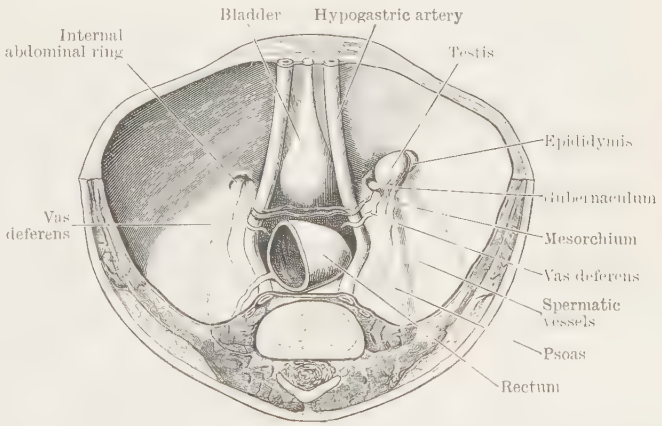

Fig. 834.—View looking from above into the Pelvis and Lower Part of the Abdominal Cavity in a Fœtus of about the Seventh Month.

On the left side, which represents a slightly more advanced condition than the right, the testis has entered the inguinal canal; on the right side the testis is still within the abdominal cavity.

Often a small fibrous band—the **ligamentum vaginale**—may be found in the adult passing through the inguinal canal and joining the peritoneum superiorly in the region of the internal abdominal ring. Sometimes the ligament is connected below with the tunica

vaginalis, but more often it does not reach so far downwards. When present it represents the obliterated portion of the processus vaginalis (rudimentum processus vaginalis).

In other rare cases the processus vaginalis may persist after birth as a channel freely open to the abdominal cavity above, or the passage, becoming closed at intervals, may give rise to one or more cysts within the coverings of the spermatic cord.

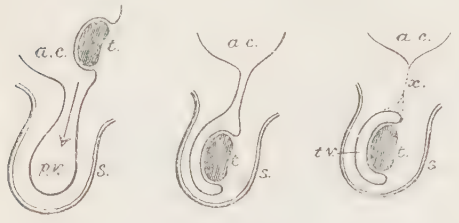

Fig. 835.—Diagram to illustrate the descent of the testis and the manner in which the tunica vaginalis is derived.

*a.c.* Abdominal cavity.
*p.v.* Processus vaginalis.
*t.* Testis.

*t.v.* Tunica vaginalis.
*x.* Ligamentum vaginale.

It sometimes happens that the descent of the testis is arrested, and then, either failing to enter the processus vaginalis, the testis remains within the abdominal cavity; or entering the processus vaginalis, it fails to reach the scrotum, and lies in the inguinal canal. The term cryptorchism is frequently applied to such cases.

In connexion with the descent of the testis a remarkable cord-like structure—the **gubernaculum testis**—must be mentioned. The gubernaculum arises for the most part within a peritoneal fold which, at an early time in the development of the fœtus, may be seen stretching from the inguinal region to the Wolffian duct (future duct of testis) and lower end of mesonephros (primitive kidney). This peritoneal fold, termed the **plica inguinalis** (or plica inguino-mesonephrica), is joined from above by a less marked fold (the plica testis inferior) which extends downwards from the lower end of the testis,—at this time situated in the abdomen close to the inner aspect of the mesonephros. Within both these folds smooth muscular and fibrous tissue arises and gives origin to a continuous band or ligament—the gubernaculum testis. The gubernaculum is, therefore, to be regarded as originally composed of two portions,—a part developed within the plica inguinalis and a part formed within the plica testis inferior. It is interesting to note that the representatives of these two parts of the gubernaculum remain separate in the female throughout life, and are the round ligament of the uterus and the ligament of the ovary. The gubernaculum, when it is at its greatest development (about the sixth month), is rounded and cord-like, and is attached above to the lower end of the testis, while inferiorly it is fixed near the inguinal region. In the lower part of its course it is closely related to, and is partly covered by, the peritoneum of the processus vaginalis. Striped muscular fibres are present in the lower part of the gubernaculum, and these have their origin from the muscles of the inguinal part of the anterior abdominal wall. As the testis enters the processus vaginalis the gubernaculum atrophies, but at birth a short part of the gubernaculum may still be found passing downwards towards the lower part of the scrotum and lying below the level of the tunica vaginalis. It is considered by some anatomists that the movement downwards of the testis may be partly due to a pull caused by the shrinking of the gubernaculum as it atrophies.

In some mammals, such as the elephant, the testes remain permanently within the abdominal cavity; while in others, such as the rabbit and the hedgehog, the peritoneal pouches remain widely open throughout life, and the testes are periodically withdrawn into the abdomen.

## The Spermatic Cord.

The testis in its course downwards through the abdominal wall into the scrotum takes with it its duct (vas deferens), blood-vessels, lymphatics, and nerves of supply. All these lie together in the inguinal canal as they traverse the abdominal wall, and when they leave the canal by the external abdominal ring they extend downwards to the posterior border of the testis. The vas deferens, the spermatic vessels, and the nerves and lymphatics of the testis, loosely connected together, form the **spermatic cord** (funiculus spermaticus). At the internal abdominal ring the constituent parts of the cord separate from one another, and the cord may therefore be considered to extend from the internal abdominal ring to the posterior border of the testis. The structures which form the cord are enclosed within a number of coverings derived from the layers of the anterior abdominal wall, and these, when the constituents of the cord reach the posterior border of the testis, surround the tunica vaginalis, and so form a part of the wall of the scrotum. The sheaths or coverings of the cord derived from the abdominal wall are three in

number, and are named intercolumnar fascia, cremasteric fascia, and infundibuliform fascia. The **intercolumnar fascia** is the most superficial of the three sheaths and is derived from the aponeurosis of the external oblique muscle, with which it is continuous round the margins of the external abdominal ring. The **cremasteric fascia** consists partly of muscular fibres derived from the lower part of the internal oblique muscle, and partly of delicate connective tissue. The muscular fibres pass down over the cord, and form a series of loops round the testis and tunica vaginalis. The **infundibuliform fascia** is derived from the fascia transversalis of the abdomen. It passes downwards over the cord and encloses its various structures, together with a certain amount of areolar tissue derived from the sub-peritoneal tissue of the abdominal wall and some smooth muscle fibres, in a continuous sheath.

In addition to the structures enumerated above, the artery to the vas, the cremasteric artery, and the genital branch of the genito-crural nerve, accompany the structures forming the spermatic cord.

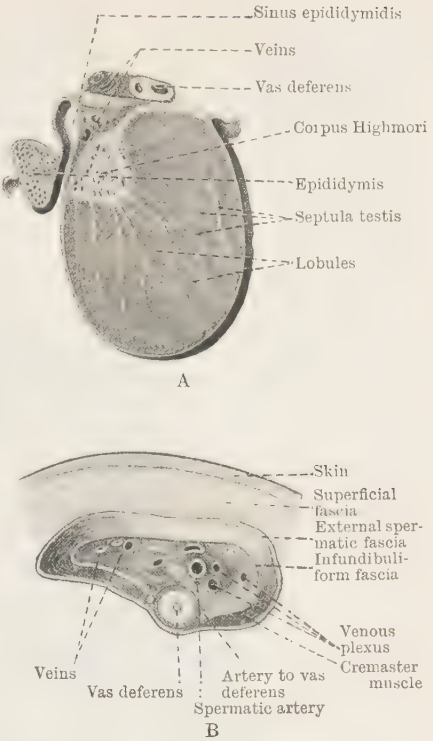

FIG. 836.

A. Transverse section of testis and epididymis.
B. Transverse section of spermatic cord below external abdominal ring.

## THE SCROTUM.

The **scrotum**, in which the testes are placed, varies much in appearance in different subjects, and even in the same individual, at different times. As the result of cold or of exercise, the wall of the scrotum becomes contracted and firm, and the skin covering it wrinkled; at other times the wall may be relaxed and flaccid, the scrotum then assuming the appearance of a pendulous bag. The left side of the scrotum reaches to a lower level than the right, in correspondence with the lower level of the testis on that side of the body. The skin covering the scrotum is of a darker colour than the general skin of the body, and is covered by hair. It is marked in the middle line by a median **raphe** (raphe scroti), which is continued backwards towards the anus, and for-

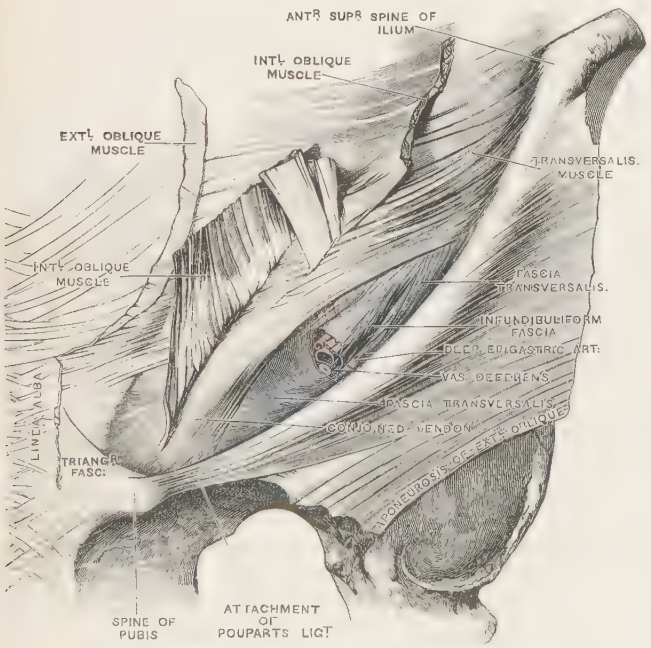

FIG. 837.—DEEP DISSECTION OF THE INGUINAL REGION.

The external and the internal oblique muscles have been reflected to show the whole length of the inguinal canal, and the cord enclosed within the infundibuliform fascia is seen cut across. (From Cunningham.)

wards on to the under, or urethral, surface of the penis. The difference in the appearance of the scrotum at different times is due to the amount of contraction, or relaxation of a layer of muscular fibres, constituting the **dartos muscle**, situated in the superficial fascia. When this muscular layer is contracted, the scrotum becomes smaller and somewhat globular, and the skin is thrown into folds or wrinkles called rugæ; when it is relaxed, the scrotum is flaccid and pendulous, and the skin becomes more smooth and even. The layer of fascia which contains the smooth muscle fibres of the dartos muscle is often spoken of as the **tunica dartos**. It can be shown to be continuous superiorly with the superficial fascia of the penis, and with the deep layer of the superficial fascia of the abdomen, and to be attached laterally to the bones forming the pubic arch. The muscle fibres are arranged in a thick layer of interlacing bundles, and many of the deeper fibres are continued into a **septum** (septum scroti) which divides the scrotum into two cavities, one for each testis. The wall of each of these cavities is formed by the corresponding tunica vaginalis, infundibuliform fascia, cremasteric fascia, and intercolumnar fascia, while the skin, the superficial fascia, and the superficial part of the dartos muscle form coverings which are common to the whole scrotum, and enclose both cavities. The layer of tissue immediately beneath the dartos tunic is made up of exceedingly loose and easily stretched areolar connective tissue, and in it as throughout in the superficial fascia of the scrotum there is an entire absence of fat.

The scrotum in the fœtus contains no cavity, but, like the labia majora in the female, it is composed entirely of vascular connective tissue.

**Vessels and Nerves of the Scrotum.**—The scrotum receives its vascular supply from the **superficial perineal branches** of the internal pudic arteries which reach it from behind, and from the **external pudic branches** of the femoral artery which reach its upper and anterior part. The nerves of the scrotum are derived from the **superficial perineal branches** of the internal pudic, from the **perineal branch** of the small sciatic, and from the **ilio-inguinal nerve**. The branches from the internal pudic and sciatic nerves reach the scrotum from behind, while the ilio-inguinal supplies its upper and anterior part. The nerve fibres for the dartos muscle fibres are believed to come from the hypogastric plexus.

## THE PENIS.

The **penis** is composed chiefly of erectile tissue, and is traversed by the canal of the urethra. The surface nearest to which the canal of the urethra lies is called the **under** or **urethral surface** (facies urethralis); the opposite and more extensive aspect is the **dorsum penis**. The erectile tissue is for the most part disposed in three longitudinal columns, which in the body of the organ are placed side by side, while at the root of the penis they separate from one another, and become attached to the triangular ligament and the pubic arch. Two of these masses of erectile tissue, placed one on each side of the middle line, and forming the dorsum and sides of the penis, are called the **corpora cavernosa** (corpora cavernosa penis), while the third, which is called the **corpus spongiosum** (corpus cavernosum urethræ), is situated mesially near the urethral surface. The corpus spongiosum is the part of the penis which is traversed by the urethra, and it is considerably smaller than the corpora cavernosa which form the chief bulk of the organ.

In the **body of the penis** (corpus penis) each corpus cavernosum is placed close to the mesial plane, and presents a rounded surface, except where it is flattened by contact with its fellow of the opposite side. The corpora cavernosa are separated on the anterior (dorsal) surface by a shallow groove, and on the posterior (urethral) aspect by a deeper and wider furrow, in which lies the corpus spongiosum (Fig. 839). Towards the distal end of the penis the corpus spongiosum appears to expand, and, spreading towards the dorsal surface of the organ, it forms a kind of conical cap, the **glans penis**, which covers over the blunt rounded termination of the corpora cavernosa. The prominent margin of the glans, called the **corona glandis**, projects dorsally and laterally beyond the extremities of the corpora cavernosa. Like the corpus spongiosum the glans is traversed by the urethra, which ends near the summit of the glans in a slit-like opening called the **meatus urinarius**, or external urethral orifice. The united corpora cavernosa end in a blunt

conical extremity, the apex of which is received into a hollow in the base of the glans. The skin covering the body of the penis is thin, delicate, and freely movable, and, except near the root of the organ, is free from hairs; on the urethral aspect of the penis the skin is marked by a median raphe, continuous with the raphe of the scrotum. Traced towards the base of the glans, the skin forms a free fold called the **prepuce** (præputium), which overlaps the glans to a variable extent. From the deep surface of the prepuce the skin is reflected on to the terminal part of the penis, just above the level of the corona glandis, and is continued over the

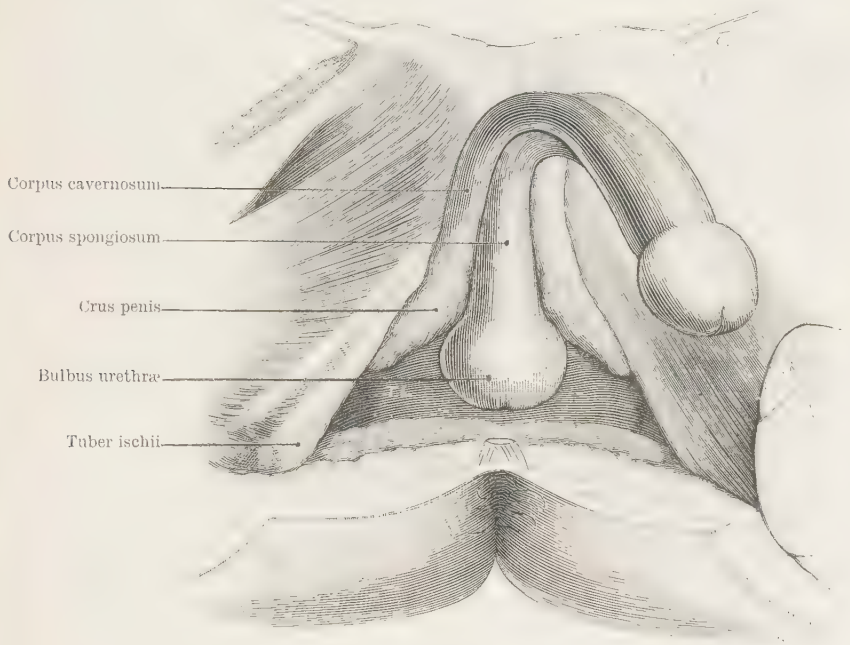

FIG. 838.—DISSECTION TO ILLUSTRATE THE COMPONENT PARTS OF THE PENIS.

On the right side of the figure the muscles of the thigh have been reflected down to the plane of the obturator externus. The letters TL are placed upon the triangular ligament.

entire glans to the meatus urinarius. A small median fold, the **frenulum præputii**, passes to the deep surface of the prepuce from a point just below the meatus urinarius. The skin covering the glans is firmly attached to the underlying erectile tissue, and here, as well as on the deep surface of the prepuce, it presents some resemblance to mucous membrane.

Sometimes minute sebaceous glands (glandulæ præputiales) are found in very variable numbers on the glans and inner surface of the prepuce; the secretion from these when they are present may help to form the **smegma præputii**, which tends to collect in the groove between the glans and the prepuce. The main source of the smegma is to be found in the desquamated and broken-down epithelial cells derived from the surface of the glans and prepuce.

At the **root of the penis** (radix penis) the three component parts of the organ separate from one another (Fig. 838). The corpora cavernosa, diverging from each other laterally, at first become somewhat swollen, and then, gradually tapering off, gain a firm, fibrous attachment to the periosteum on the inner part of the pubic arch. These diverging parts of the corpora cavernosa are called the **crura penis**, and each is covered by the corresponding ischio-cavernosus muscle. The corpus spongiosum lying between the crura becomes enlarged, and forms a somewhat spherical mass which receives the name **bulb of the urethra** (bulbus urethræ). The bulb varies much in size in different individuals, and is attached to the under surface of the triangular ligament, against which it rests. The posterior part and under surface of the bulb usually show a median notch or groove, which is an indication that the bulb is originally composed of two symmetrical portions, which during

development have become fused in the middle line. These two portions are termed the **hemispheria bulbi urethræ**, and are best seen in subjects whose tissues have been hardened by intra-vascular injection. A slightly marked median septum, situated within the bulb tissue, indicates on a deeper plane the line along which fusion has taken place. The canal of the urethra, piercing the triangular ligament, enters the bulb obliquely a short distance in front of its posterior extremity (Fig. 844). Covering the superficial surface of the bulb is the bulbo-cavernosus muscle.

A somewhat triangular band of strong fibrous tissue, called the **suspensory ligament of the penis**, is attached to the front of the symphysis pubis, and extends to the fibrous capsule of the penis, with which it becomes continuous.

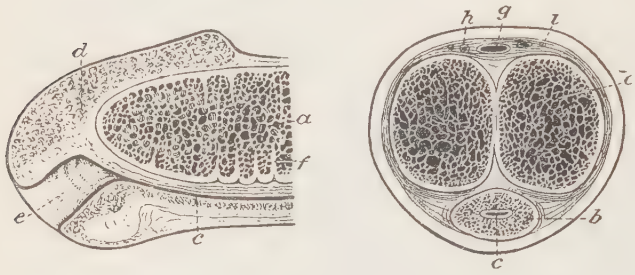

Fig. 839.—A Longitudinal Section of the Terminal Portion of the Penis, and a Transverse Section through the Body of the Organ.

*b*. Corpus spongiosum. *e*. Fossa navicularis. *h*. Dorsal artery.
*c*. Urethral canal. *f*. Part of septum pectiniforme. *i*. Dorsal nerve.

**Structure of the Penis.**—Each corpus cavernosum penis is enclosed by a dense white fibrous coat or **tunica albuginea** (tunica albuginea corporum cavernosorum), which, fusing with the corresponding coat of the opposite side, forms a mesial septum (septum penis). The septum is very incomplete, especially near the terminal part of the penis, where it is interrupted by a number of nearly parallel slit-like perforations, hence the term **septum pectiniforme** is often applied to it (Figs. 839 and 845). Through these openings the erectile tissue of the corpora cavernosa of opposite sides is continuous.

The fibrous coat contains some elastic fibres, and may be divided into an outer layer of longitudinally directed fibres and an inner layer of circular fibres, some of which latter are continued into the septum. Numerous fibrous strands, called **trabeculæ** (trabeculæ corporum cavernosorum), proceed from the deep surface of the tunica albuginea, and stretching across the interior of the corpus cavernosum, form a fine sponge-like framework whose interspaces communicate freely with one another, and are filled with blood. These blood-containing spaces lead directly into the veins of the penis, and like the veins have a lining of flat endothelial cells. The size of the penis varies with the amount of blood in this cavernous tissue. The structure of the corpus spongiosum resembles that of the corpora cavernosa, but the fibrous coat is much thinner and more elastic, and the trabeculæ are finer (Fig. 839).

The glans penis is also composed of cavernous tissue which communicates by a rich venous plexus, situated on the ventral aspect of the urethra, with the corpus spongiosum urethræ. No strongly marked tunica albuginea is present, and the erectile tissue is practically bounded by the firmly adherent skin. Surrounding the urethra, which in this part of the penis is represented by a laterally compressed slit-like passage, is a mass of fibro-elastic tissue which forms a kind of median septum within the glans. This septum is continued backwards to join the sheath of the conical end of the corpora cavernosa, and ventrally it gives attachment to the frenulum of the prepuce. It imperfectly divides the erectile tissue of the glans into right and left portions, which, however, freely communicate dorsally. From the septum trabeculæ pass out in all directions into the tissue of the glans.

Loosely surrounding the corpora cavernosa and the corpus spongiosum is a fibrous sheath containing numerous elastic tissue fibres. This sheath is termed the *fascia penis* and reaches as far as the base of the glans, where it becomes fixed to the floor of the groove limited by the corona glandis. In its proximal part the sheath gives insertion to many of the fibres of the bulbo-cavernosus and ischio-cavernosus muscles.

Superficial to the fascia penis is a layer of extremely lax areolar tissue, and more superficial still is a prolongation of the dartos muscle of the scrotum (dartos penis) and the delicate skin of the penis. Numerous sebaceous glands are present in the skin, especially on the urethral aspect of the penis.

In some mammals, such as the walrus, dog, bear, baboon, etc., a bone called the **os penis** is developed in the septum which intervenes between the corpora cavernosa.

**Vessels and Nerves of the Penis.**—The penis receives its arterial supply from branches of

the internal pudic artery. The erectile tissue of the corpora cavernosa is supplied chiefly by the **deep arteries of the penis**, while that of the corpus spongiosum receives its arterial supply from the **artery to the bulb**. Branches of the **dorsal artery** of the penis piercing the fibrous coat of the corpora cavernosa furnish additional twigs to the erectile tissue of these structures. The glans receives its chief blood supply from branches of the dorsal artery. The small branches of these arteries run in the trabeculæ of the erectile tissue, and the capillaries, into which they lead, open directly into the cavernous venous spaces. As they lie in the finer trabeculæ the smaller branches often present a peculiar twisted appearance, and hence the name **helicine arteries** (arteriæ helicinæ) is sometimes applied to them.

The veins with which the cavernous spaces communicate carry the blood, for the most part, either directly into the **prostatic plexus**, or into the **dorsal vein**, and so to the prostatic plexus. The dorsal vein of the penis begins in tributaries from the glans and prepuce, and lies in the groove between the corpora cavernosa as it ascends to pass beneath the sub-pubic ligament and join the prostatic plexus. On each side of it lies the dorsal artery, and still farther from the middle line the dorsal nerve (Fig. 839).

The **lymphatics** of the penis are arranged in a deep and superficial series and end in the inner glands of the inguinal group.

The nerve-supply of the penis is derived from the internal pudic nerve and from the **hypogastric and pelvic plexuses**. The branches of the internal pudic are the **dorsal nerve** of the penis, and branches from the **superficial perineal nerves**. These supply the cutaneous structures of the penis, while the sympathetic filaments from the hypogastric and pelvic plexuses, which reach the penis through the prostatic plexus, end in the erectile tissue.

## THE PROSTATE.

The **prostate** (prostata) is a partly glandular, partly muscular organ of a dark brown-red colour which surrounds the beginning of the urethra in the male. It lies within the pelvis behind the pubes, and is enclosed by a dense capsule derived from the pelvic fascia. Through the various connexions of this capsule the prostate is firmly fixed within the pelvic cavity. The common ejaculatory ducts traverse the prostate in their course downwards and forwards to join the urethra as it descends through the gland (Fig. 831). The size of the prostate varies considerably in different individuals, but its transverse or longest diameter is usually from one and a quarter to one and a half inches; its antero-posterior diameter about three-quarters of an inch; and its vertical diameter about one and a

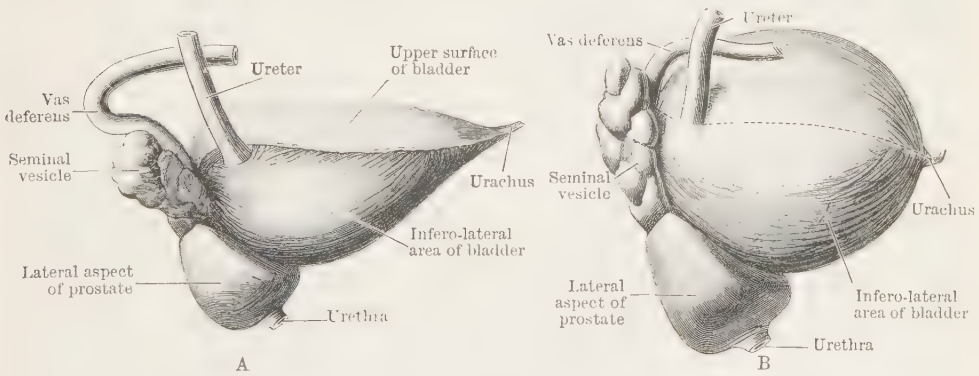

FIG. 840.—BLADDER, PROSTATE, AND SEMINAL VESICLES VIEWED FROM THE OUTER SIDE.

Drawn from specimens hardened *in situ*.

quarter inches. Superficially the prostate is separated from the bladder by deep wide lateral grooves directed downwards and forwards, and by a narrow posterior groove which is horizontal.

In connexion with the prostate we describe an apex which is directed downwards, a base looking upwards, a posterior, and two lateral surfaces. The general outline of the organ has been often compared with that of a Spanish chestnut. The upper surface, or **base** of the prostate (basis prostatæ) is directed upwards against the under aspect of the bladder, in the neighbourhood of its urethral opening. The greater part of this surface is structurally continuous with the bladder wall, only a narrow portion remains free on each side, and forms the lower limit of the deep groove which marks the separation of the bladder and prostate

(Fig. 840). The **lateral surface** of the prostate is convex and prominent, especially in its posterior and upper portion, and rests against the fascia covering the levator ani muscle. The lateral surfaces are directed for the most part outwards, downwards, and somewhat forwards, and meet together in front in a rounded anterior border, often called the "**anterior surface**" (facies anterior) of the prostate. Posteriorly the prostate presents a flattened somewhat triangular area, directed backwards and downwards against the anterior wall of the rectum, from which it is separated by a layer of the pelvic fascia. This flattened **posterior surface** (facies posterior) is separated on each side from the lateral surface by a rounded border which, beginning above at the prominent lateral part of the prostate, ends below at the apex of the organ. The **apex** of the prostate (apex prostatæ) points downwards, and is in relation to the compressor urethræ muscle, from which it is separated by the pelvic fascia. From the apex the rounded anterior border, which separates the lateral surfaces, passes upwards in the middle line behind the symphysis pubis and retro-pubic pad of fat. This border is interrupted in its lower part by the passage of the urethra.

When the capsule formed by the pelvic fascia is stripped off the prostate the organ has a more rounded outline, and the surfaces just described are not so clearly defined. The anterior border may now appear to be rather a surface than a border, and the antero-posterior diameter of the whole organ is considerably reduced.

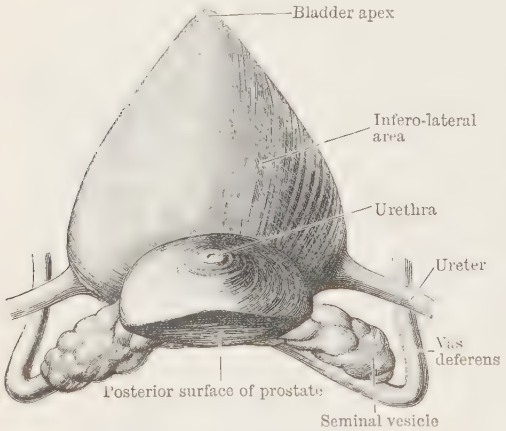

FIG. 841.—PROSTATE, BLADDER, AND SEMINAL VESICLES SEEN FROM BELOW.

Drawn from a specimen hardened *in situ*. The lateral surfaces of the prostate are seen one on each side of the urethra and in front of the posterior surface.

The urethra enters the prostate at a point near the middle of its upper surface, and leaves it at a point situated on its anterior border, just above and in front of the apex. As it descends, the urethra describes a curve which is concave forwards, and in mesial section it is seen to lie on the whole nearer to the posterior surface than to the anterior border of the gland.

The common ejaculatory ducts, entering a slit-like interval or hilum situated just in front of the border which separates the base from the posterior surface of the prostate, run downwards, inwards, and forwards, to open into the prostatic portion of the urethra very close to one another. The somewhat wedge-shaped portion of the prostate, which lies between these ducts and the posterior aspect of the urethra, receives the name of **middle lobe** (lobus medius, Fig. 845). The base of this middle lobe projects upwards against the bladder, and is continuous with the part of the bladder wall lying immediately behind the urethral orifice. When hypertrophied (as it often is in old people) the middle lobe of the prostate may cause a considerable elevation in the cavity of the bladder, to which the term uvula vesicæ is applied, and which possesses considerable surgical interest. The rest of the prostate is described as being composed of two large lateral portions or **lateral lobes**, which are, however, not marked off from one another superficially.

In front of the prostate, between it and the pubis, is a rich venous plexus in which the dorsal vein of the penis terminates. This plexus is continued backwards, on each side, round the lateral aspect of the prostate and joins the large thin-walled veins which are collected for the most part in the deep sulcus between the bladder wall and the prostate, and form the prostatico-vesical plexus. Most of the veins forming this plexus lie partly within and partly outside the dense fibrous capsule of the prostate, which is derived from the visceral pelvic fascia (Figs. 842 and 843).

The **fibrous capsule of the prostate** is formed by the visceral pelvic fascia, and closely invests the gland on its lateral and posterior aspects. Inferiorly at the apex of the prostate this capsule becomes continuous with the layer of fascia which

lies above the compressor urethræ muscle, and is attached to the pelvic arch. In front two thickened bands pass forwards from the anterior aspect of the capsule, one on each side of the middle line, to reach the back of the lower part of the pubis where they are attached to the periosteum. These constitute the pubo-prostatic ligaments, and contain smooth muscle fibres as well as dense connective tissue. Some of the muscle fibres in connexion with the pubo-prostatic ligaments passing upwards as well as backwards, gain the bladder wall and are spoken of as the pubo-vesical muscles. Below the pubo-prostatic ligaments the inner edges of the levatores

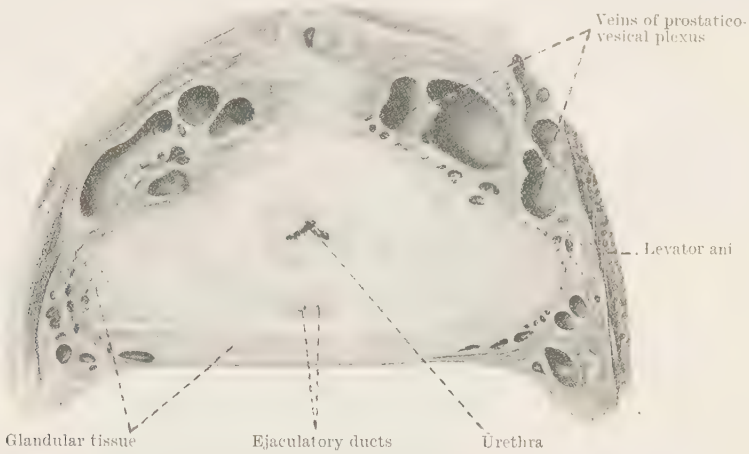

Fig. 842.—Transverse Section through the Prostate, just below its junction with the bladder. About twice natural size.

ani muscles pass inwards and meet together in front of the apex of the prostate. When followed backwards, the inner edges of these muscles are seen to closely embrace the apex of the prostate.

Between the pubo-prostatic ligaments there is a shallow fossa, or depression, the floor of which is formed by a thin layer of fascia connecting the anterior aspect of the capsule of the prostate with the back of the pubis. When the fibrous capsule of the prostate is traced upwards beyond the level of the upper margin of the gland it becomes thinned out and joins the facial covering of the bladder. Posteriorly the upward prolongation of the capsule is continuous with the facial layers which enclose the ampullæ of the vasa deferentia and the seminal vesicles, and it is adherent to the peritoneum of the recto-genital pouch. In this position it is often spoken of as the recto-vesical fascia.

**Structure of the Prostate.**—Beneath the fibrous capsule of the gland the superficial part of the prostate is seen to be largely composed of matted interlacing bundles of smooth muscle and connective tissue fibres, which form a kind of sheath for the deeper parts of the organ. This layer or sheath is not sharply defined, but from its deep aspect fibrous and muscular strands pass inwards, converging towards the posterior wall of the urethra, to become continuous with the mass of smooth muscular tissue which surrounds this canal as it traverses the prostate. These somewhat radially arranged strands divide the prostate into a number of incompletely defined lobules of which there appear to be about fifty. The yellowish-coloured glandular tissue (corpus glandulare) which forms these lobules is composed of minute, slightly branched tubules, the walls of which in certain places show numerous saccular dilatations. In the upper portion of the gland the tubules are slightly dilated and shorter than in the lower part, where they are longer and more convoluted. The glandular tubules lead into the minute prostatic ducts, which open into the urethral canal as it traverses the prostate. These ducts (ductus prostatici) number about twenty or thirty, and open for the most part into a groove on each side of the median elevation (crista urethralis) in the posterior wall of the urethra (Fig. 846).

The bulk of the glandular tissue is situated at the sides of and behind the

urethra. In front of the upper part of the prostatic portion of the urethra there is a mass of smooth muscular fibres, which is continued upwards and backwards on the sides of the urethra to form a part of the sphincter vesicæ. At a lower level striped muscular tissue, which is continuous with the deep part of the compressor urethræ muscle, occupies a position in front of the urethral canal.

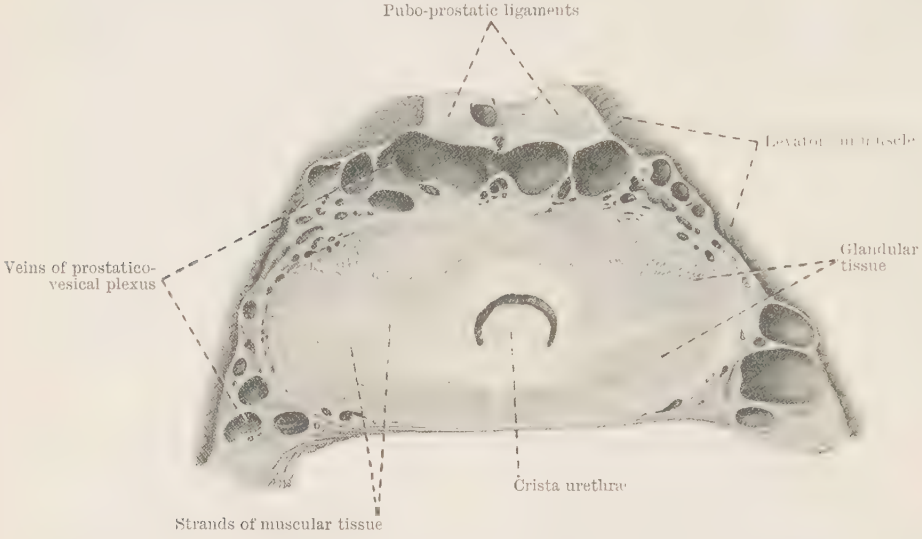

Fig. 843.—Transverse Section through the Prostate, about half-way between its apex and base.

The muscular tissue of the prostate may be regarded as the thickened muscular layer of the wall of the urethra, which has become broken up and invaded by the prostatic glands, which arise and are developed from the lining layer of the canal during embryonic life.

In old age the prostate frequently undergoes an hypertrophy, which may affect chiefly the glandular tissue, or the entire organ. Not infrequently calcareous concretions are found embedded in the prostate.

**Vessels and Nerves of the Prostate.**—The prostate receives its blood-supply from branches of the **hæmorrhoidal** and **inferior vesical arteries,** while the large plexus of veins which surrounds it, and into which the veins of the penis open, communicates with the **vesical plexus,** and drains into the internal iliac veins. In old people the veins of the prostatic plexus usually become much enlarged. The nerves of the prostate are derived from the **hypogastric plexus.**

## COWPER'S GLANDS.

**Cowper's glands** (glandulæ bulbo-urethrales) are a pair of small bodies placed in relation to the second, or membranous, part of the urethra. They are each about the size of a pea, and are of a yellowish-brown colour. Situated in the space between the two layers of the triangular ligament, they lie below the level of the apex of the prostate, and above that of the bulb of the corpus spongiosum (Figs. 844 and 846). The gland is made up of a number of closely applied lobes or lobules, and is of the compound racemose type. The ductules of each gland unite to form a single duct (ductus excretorius), which pierces the bulb of the corpus spongiosum, and, after a relatively long course, ends by opening into the spongy portion of the urethra by a minute aperture. The secreting acini are lined by columnar epithelium.

The glands receive their arterial supply from the artery to the bulb.

In old age these glands are often difficult to find.

## THE MALE URETHRA.

The **urethra** in the male is a channel of about eight inches in length leading from the bladder to the external urethral orifice at the extremity of the glans penis. The canal serves not only for the passage of urine, but it also affords an exit for the seminal products which enter by the common ejaculatory ducts, and for the secretion of the prostatic and Cowper's glands. In addition, numerous minute glands (glandulæ urethrales) pour their secretion into the urethra.

As it passes from the internal urethral orifice, to its external opening, the

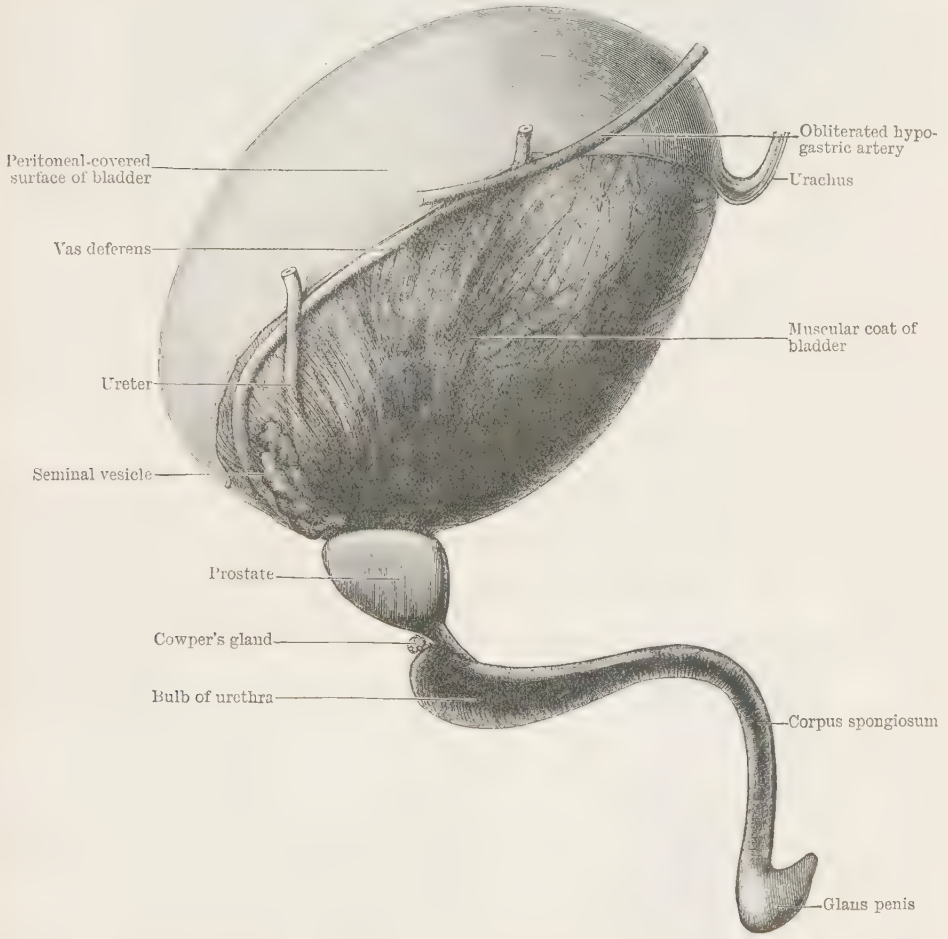

FIG. 844.—THE BLADDER AND THE STRUCTURES TRAVERSED BY THE URETHRA, seen from the outer side after removal from the body. The bladder has been artificially distended.

urethra describes a somewhat S shaped course, and it is customary to divide it into certain sections which have received distinctive names. The first part of the urethra lies within the pelvic cavity, and has an almost vertical course as it traverses the prostate. Turning more forwards, the urethra passes below the pubic arch, and pierces the fibrous layers which form the pelvic wall in this region. Leaving the pelvic cavity, the canal enters the bulb of the corpus spongiosum, where the latter is attached to the triangular ligament, and throughout the rest of its course it lies in the erectile tissue of the corpus spongiosum and glans penis. The part of the urethra which lies embedded in the prostate is called the **prostatic portion**; the short portion which pierces the pelvic wall is called the **membranous portion**, and the part surrounded by the corpus spongiosum receives the name of **spongy portion**. Of these three sections of the urethra the spongy portion is much the longest, and the membranous is the shortest.

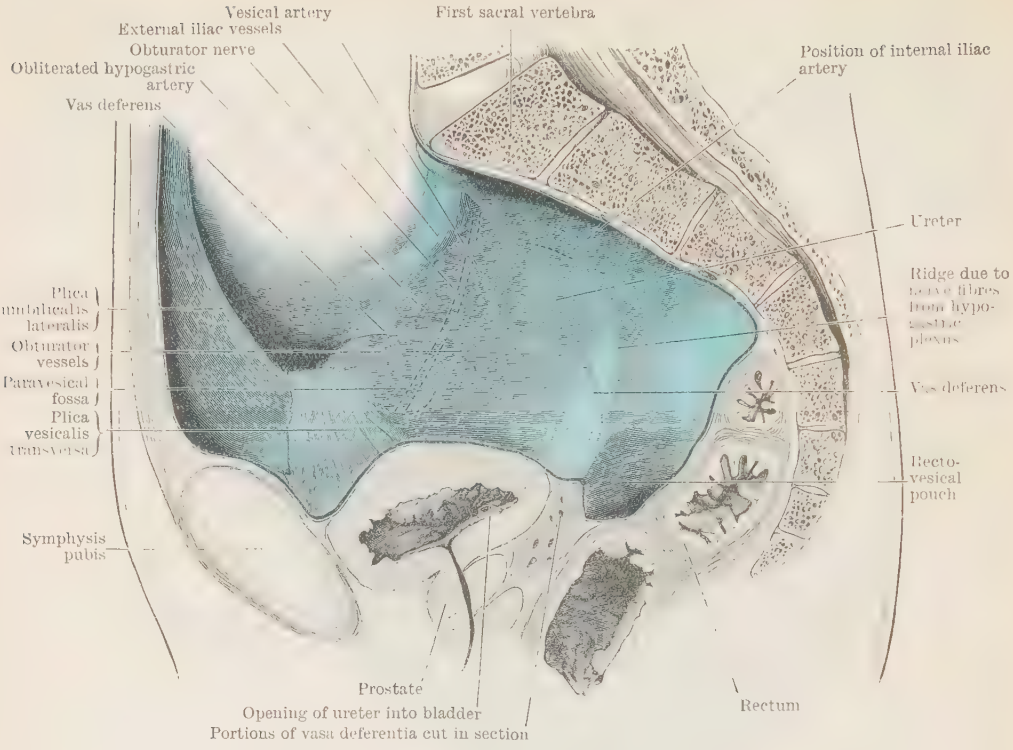

FIG. 845.—MESIAL SECTION OF AN ADULT MALE PELVIS.

The coils of the small intestine and of the pelvic colon which lay within the pelvis have been lifted out in order to give a view of the side wall of the pelvic cavity. The peritoneum is coloured blue.

Developmentally the spongy portion of the urethra has a different origin from the other subdivisions, as it is derived from the ectodermal cloacal fossa, while the prostatic and membranous portions owe their origin to the urinogenital canal,—a derivative of the endodermal cloaca.

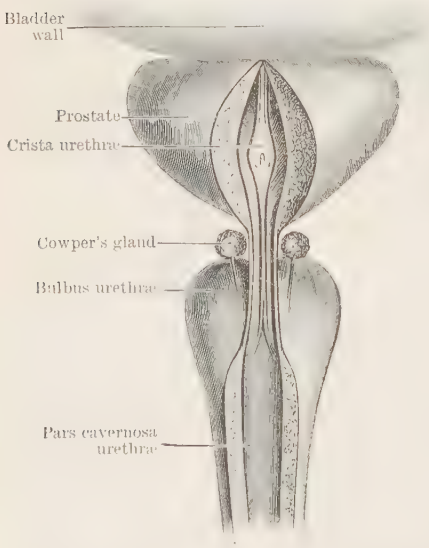

FIG. 846.—THE PROSTATIC, MEMBRANOUS, AND THE UPPER PORTION OF THE SPONGY URETHRA, opened from in front and above to show the posterior wall or floor. The minute openings of the common ejaculatory ducts and the orifice of the sinus pocularis are seen upon the crista urethræ.

**Prostatic Portion of the Urethra.**—The prostatic part (pars prostatica) of the urethra descends through the prostate from the base towards the apex, describing a slight curve which is concave forwards. It is about one inch in length, and is narrower above and below than in its middle portion, which is indeed the widest part of the whole urethral canal. Except while fluid is passing, the canal is collapsed, and the mucous membrane of the anterior and posterior walls is in contact, and thrown into a series of longitudinal folds. When distended, the middle, or widest part of the canal, may normally have a diameter of about one-third of an inch. The posterior wall, often termed the "floor" of the prostatic urethra, presents a distinct mesial ridge or elevation called the **crista urethræ** (crista urethralis) or **verumontanum** (Fig. 846). This projects forwards into the urethra to such an extent that the canal in transverse section presents a somewhat crescentic outline. In the depres-

sions or grooves on each side of the crista urethræ the numerous ducts of the prostatic glands open by minute apertures. Some few ducts from the middle part of the gland open nearer the middle line, on the sides of the urethral crest. On the summit of the crista urethræ is a slit-like opening which leads backwards and upwards for a distance of about a quarter of an inch, as a blind pouch, in the substance of the prostate. This little cavity is the **prostatic utricle** (utriculus prostaticus) or **sinus pocularis**, and represents the fused posterior ends of the Müllerian ducts from which the uterus and vagina of the female are developed. The term uterus masculinus is therefore sometimes applied to this little pouch. On each side of the mouth of the utricle is the much more minute opening of the common ejaculatory duct. When traced upwards towards the bladder, the urethral crest, diminishing in height, becomes indistinct, but in it can often be traced as a slight median ridge as far as the uvula vesicæ. When followed in the opposite direction the ridge becomes less marked, and can be followed on the urethral wall into the membranous portion of the canal, where it divides into a pair of inconspicuous folds or elevations, which gradually fade out into the urethral wall (Fig. 846).

The curvature and, to a less degree, the length of the prostatic urethra depends upon the amount of distension of the bladder and of the rectum.

**Membranous Part of the Urethra.**—The second or membranous portion (pars membranacea) of the urethra leads downwards and forwards from the apex of the prostate to the bulb of the corpus spongiosum, and is the shortest and narrowest of the three subdivisions of the canal, its length being somewhat less than half an inch. It begins at the deep layer of the triangular ligament, a layer of pelvic fascia which lies above the compressor urethræ muscle, where it is continuous with the prostatic portion, and ends, having pierced the superficial layer, by becoming continuous with the spongy portion of the urethra. Placed in front of the rectum, it lies about one inch behind and below the sub-pubic ligament, and is surrounded by fibres of the compressor urethræ muscle. Behind it, on each side of the mesial plane, are Cowper's glands. The posterior part of the bulbus urethræ projects backwards and overlaps to a considerable extent the posterior wall of the second, or membranous, part of the urethra.

The membranous portion of the urethra is the most firmly fixed and least dilatable part of the passage.

A slight median elevation, which is continuous above with the crista urethræ, projects into the canal from its posterior wall, and becoming less marked as it is traced downwards, is often seen to divide into two faint ridges. When the canal is empty other longitudinal folds or ridges are usually to be seen on the mucous membrane, but these become obliterated when the passage is distended. The lumen of the empty tube, in transverse section, presents a stellate outline.

The terminal portion of the membranous urethra, where it is overlapped posteriorly by the urethral bulb, lies in front of the triangular ligament. It is considerably wider than the upper part of this subdivision of the canal, and is very thin-walled (Figs. 844 and 845).

**Spongy Portion of the Urethra.**—The third or spongy portion (pars cavernosa) of the urethra is much the longest of the three subdivisions. It begins at a point about half an inch in front of the posterior end of the bulb, and ends at the external orifice on the glans penis. Its proximal or perineal portion has a fixed position and direction, while its distal part varies with the position of the penis. The canal is about six inches in length, and is related throughout its whole extent to the erectile tissue of the corpus spongiosum and glans. Directed at first forwards through the bulb of the corpus spongiosum, the canal turns downwards and forwards at the point where it comes to lie in front of the lower part of the symphysis pubis (Fig. 845). This bend in the direction of the canal, roughly speaking, corresponds to the place of attachment of the suspensory ligament to the dorsum of the penis. When the penis is drawn upwards towards the front of the abdomen, the direction of the terminal half of the canal is of course changed, and at the same time the whole length of this subdivision of the urethra becomes more uniformly curved. The urethra passing obliquely downwards and

forwards enters the bulb at a point nearly half an inch from its posterior extremity. Immediately after the canal has pierced the triangular ligament its posterior aspect becomes surrounded by the erectile tissue of the bulb, but the anterior wall remains uncovered for a distance of about a quarter of an inch (Figs. 844 and 845). The wall of the urethra is here very thin, and the passage is more readily dilatable than in other parts. In this region the urethral wall may readily be torn through, if undue force is used, or if the handle is depressed too soon when attempting to pass an instrument into the narrower more fixed membranous part of the canal. The urethra lies at first in the upper part of the erectile tissue, but as it passes forwards it sinks deeper, and comes to occupy the middle part of the corpus spongiosum (Fig. 845). In the glans, on the other hand, the erectile tissue lies on the dorsal and lateral aspects of the urethra. Like the other parts of the urethra the canal is closed except during the passage of fluid, the closure being effected by the apposition of its dorsal and ventral walls except in the part of the canal which lies in the glans penis, where the lateral walls of the canal come into contact (Fig. 847). Thus the lumen of the first part of the canal, when empty, is represented in cross section by a transverse slit, and that of the terminal part by a vertical slit. The spongy part of the urethra does not present a uniform calibre throughout, but is narrower in its intermediate part, where it traverses the corpus spongiosum, than it is in those portions of its course which are surrounded by the bulb and the glans. The terminal dilated part of the passage is termed the **fossa navicularis urethræ**, and opens on the surface by the vertically-placed slit-like **external urethral orifice** (orificium urethræ externum), which is bounded by lateral lips, and is the narrowest and least dilatable part of the whole urethral canal.

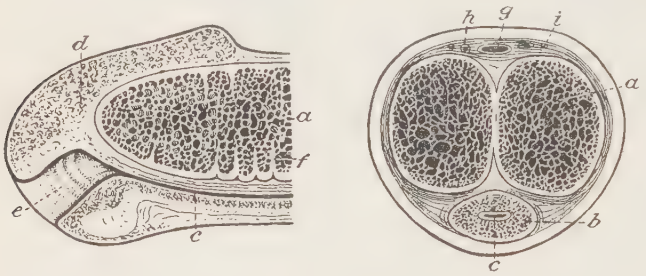

FIG. 847.—A LONGITUDINAL SECTION OF THE TERMINAL PORTION OF THE PENIS, AND A TRANSVERSE SECTION THROUGH THE BODY OF THE ORGAN.

*a*. Corpus cavernosum. *d*. Glans penis. *g*. Dorsal vein.
*b*. Corpus spongiosum. *e*. Fossa navicularis. *h*. Dorsal artery.
*c*. Urethral canal. *f*. Part of septum pectiniforme. *i*. Dorsal nerve.

The ducts of Cowper's glands open by very minute apertures in the under wall of the proximal part of the spongy portion of the urethra. Before opening into the canal, they lie for some distance immediately beneath its mucous membrane. A number of little pit-like recesses, called the **lacunæ urethrales**, also open into the spongy part of the urethra, and are so disposed that their openings lead for the most part obliquely into the canal in the direction of its external orifice.

In some cases a somewhat valve-like fold (valvula fossa navicularis) of the mucous membrane is found in the upper wall of the urethra in the region of the fossa navicularis. The free edge of this fold is directed towards the external urethral orifice, and may engage the point of a fine instrument introduced into the urethra.

**Structure.**—The mucous membrane of the urethra contains numerous elastic fibres and varies in thickness in different parts of the canal. In many positions it shows distinct longitudinal folds and also minute depressions or pits,—the lacunæ already mentioned. The lining epithelium is composed of many layers of cells, and is continuous through the internal urethral orifice with the epithelium of the bladder, which at first it closely resembles. At the fossa navicularis the lining cells, which throughout the spongy portion of the canal are of a columnar type, become flat and scaly.

Numerous minute glands, **glands of Littré** (glandulæ urethrales) open into the urethra. These are most plentiful in the upper or anterior wall, but they also occur in smaller numbers in the floor and side walls. They are most numerous in the anterior half of the spongy portion of the canal, and in the membranous subdivision of the urethra.

The larger glands are deeply placed beneath the mucous coat, and communicate with the urethra by long slender obliquely-placed branched ducts. The smaller glands lie in

the mucous coat and form flask-like depressions with very short ducts. The ducts of some of the glands open into the lacunæ, but many of the latter have no connexion with the urethral glands.

Frequently two or more elongate ducts belonging to some of the larger glands open into the urethra quite close to its termination. These are sometimes spoken of as para-urethral ducts and may be traced backwards for some distance beneath the mucous membrane forming the roof of the urethra. Morphologically they do not correspond to the ducts which in the female have received the same name.

The muscular wall in the upper part of the urethra consists of smooth muscle fibres directed for the most part longitudinally, but some circularly arranged fibres are also present. It is probable that throughout the greater part of the spongy urethra a muscular coat is not represented.

Round the beginning of the urethra there is an obliquely-placed band of circularly-arranged smooth muscle fibres, which is continued downwards and forwards from below the anterior part of the trigone of the bladder. The lower and anterior fibres of this band lie in the anterior wall of the upper part of the prostatic urethra. The band is sometimes spoken of as the sphincter vesicæ internus. At a lower level, in front of the prostatic urethra, is a band of striped muscular fibres which is continuous inferiorly with the inner circularly-disposed part of the compressor urethræ.

Like the latter it is probably to be regarded as a part of a primitive voluntary urinogenital sphincter muscle, such as is represented also in the female subject.

## THE FEMALE REPRODUCTIVE ORGANS.

The reproductive glands in the female are a pair of **ovaries** placed laterally in

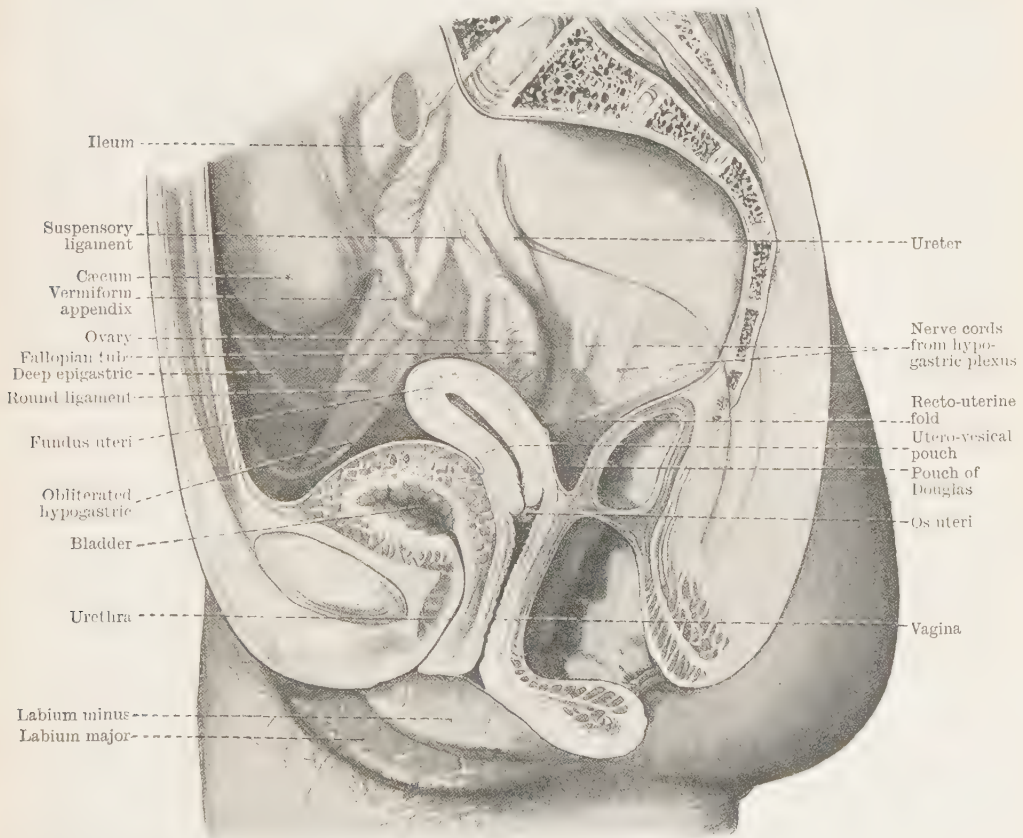

FIG. 848.—MESIAL SECTION THROUGH THE FEMALE PELVIS. Drawn for the most part from a model made from a dissection by Dr. E. H. Taylor.

the cavity of the pelvis. In connexion with each ovary is an elongated passage or tube—the **Fallopian tube**—which leads to the uterus and opens into its cavity.

There is no direct continuity between the ovary and the Fallopian tube, such as exists between the other glands of the body and their ducts, but the ova when shed from the ovary pass into the open end of the tube, and are thus conducted to the uterine cavity. The **uterus**, or **womb**, is a hollow muscular organ which occupies a nearly median position in the pelvis; it is joined by the Fallopian tubes above, and it communicates with the upper part of the vagina below. The ovum, having passed through the Fallopian tube, reaches the cavity of the uterus, and in it, if fertilisation has taken place, the ovum undergoes its development into the embryo and fœtus. The **vagina** is the passage which leads from the uterus to the exterior, and has its external opening behind that of the urethra, within the urinogenital space. In connexion with the urinogenital space are a number of structures which are included under the term **external genital organs**, and which represent in the female the various parts of the penis and scrotum in the male. These are the **labia majora** and the **mons Veneris**, the **labia minora**, the **clitoris**, and the **bulbus vestibuli**. The **glands of Bartholin**, placed one on each side of the lower part of the vagina, are accessory organs of the female reproductive system, and are represented by Cowper's glands in the male.

## THE OVARY.

The **ovary** (ovarium) is a solid body, flattened from side to side, and about the size and shape of a large almond. Its length is usually between one and one and a half inches, and the thickness from side to side between a quarter and half-an-inch. In the adult the ovary is placed against the side wall of the pelvic cavity, and is connected by peritoneal folds with the broad ligament of the uterus and with the lateral wall of the pelvis. The position occupied by the ovary within the pelvic cavity is fairly constant, although these ligaments do not hold the organ firmly fixed in any definite place.

In the ovary we recognise two poles or extremities—an *upper pole*, larger and more rounded, and a *lower pole*, somewhat pointed. The term **tubal pole** (extremitas tubaria) is applied to the upper end of the ovary, as it is most intimately connected with the Fallopian tube; the term **uterine pole** (extremitas uterina) is used with reference to the lower extremity, since this part of the ovary is connected with the uterus by a fibrous cord, termed the ligament of the ovary. The flattened *surfaces* of the ovary are called *internal* (facies medialis) and *external* (facies lateralis), and the *borders* separating them *anterior* (margo mesovaricus) and *posterior* (margo liber). The posterior border is convex and free; while the anterior one, which is straighter and narrower, is connected by a very short peritoneal fold (mesovarium) with the posterior layer of the broad ligament of the uterus. The vessels and nerves enter the ovary by this anterior border, which is therefore often termed the **hilum** of the ovary.

**Position and Relations of the Ovary.**—When the ovary occupies its most usual or typical position the long axis of the gland is vertical. Its outer or lateral surface lies against the side wall of the pelvis, and its inner surface looks inwards towards the pelvic cavity. The peritoneum of the pelvic wall, where the ovary lies against it, is depressed to form a little fossa termed the **fossa ovarica**, within which the ovary is placed. In the floor of this fossa are the obturator nerve and vessels. The upper pole of the ovary lies below the level of the external iliac vessels, and its lower end is placed just above the level of the peritoneum covering the pelvic floor. The fossa ovarica, in which the ovary lies, extends as far forwards as the obliterated hypogastric artery, and backwards as far as the ureter and uterine vessels. Thus the anterior border of the ovary lies just behind the line of the obliterated hypogastric artery, and the posterior border is on a plane anterior to the ureter (Fig. 849). The inner surface of the ovary is almost completely covered by the Fallopian tube, which, passing upwards on it near its anterior border, arches over the upper pole, and then turns downwards in relation to the posterior border and posterior part of the inner surface (Fig. 849).

In some cases the ovary is found to lie behind, or more rarely in front, of the fossa described

above, and its long axis may be oblique instead of vertical. The above description, however, corresponds to the typical position of the organ in women who have not borne children. When the uterus is much inclined towards the right side of the body the left ovary has its long axis directed obliquely downwards and inwards, the right gland remaining vertical.

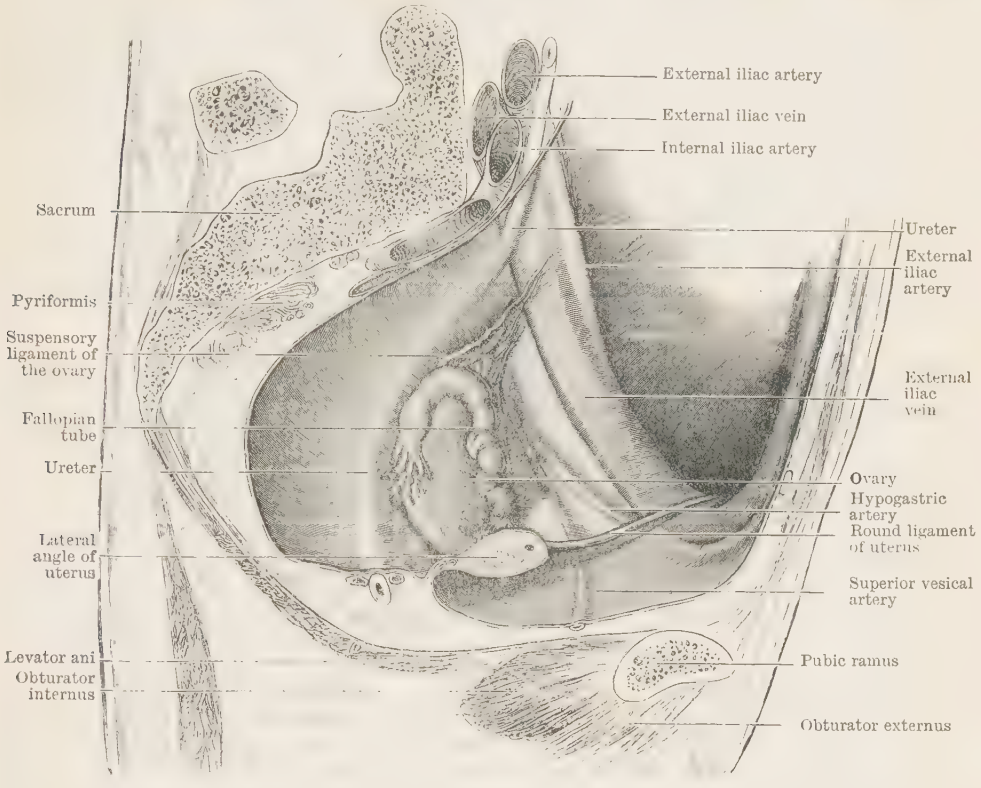

FIG. 849.—SIDE WALL OF THE FEMALE PELVIS, showing the position of the ovary and its relation to the Fallopian tube. The pelvis has been cut in section parallel to, but at some distance from, the mesial plane. Drawn from a specimen in the Anatomical Department, Trinity College, Dublin.

**Connexions of the Ovary.**—When the ovary is in position a small somewhat triangular peritoneal fold passes upwards from its upper pole, and becomes lost in

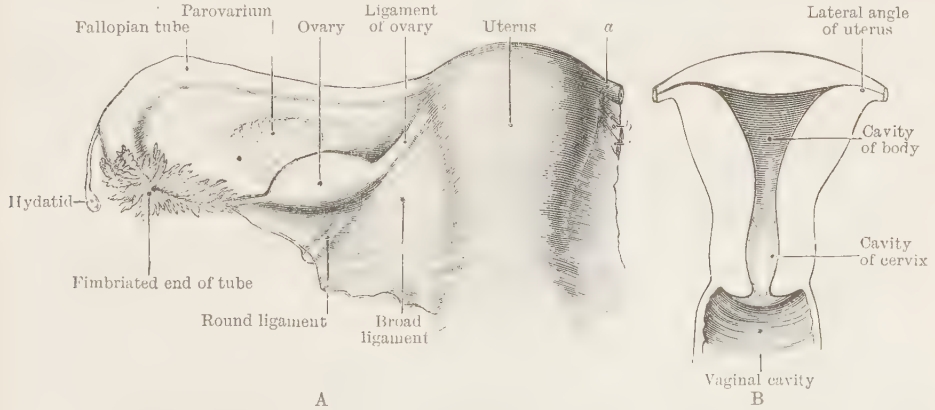

FIG. 850.—A. THE UTERUS AND BROAD LIGAMENT SEEN FROM BEHIND (the broad ligament has been spread out).

*a*, *b*, and *c*, the isthmus tubæ, the ligament of the ovary, and the round ligament of the right side cut short.

B. DIAGRAMMATIC REPRESENTATION OF THE UTERINE CAVITY OPENED UP FROM IN FRONT.

the peritoneum covering the external iliac vessels and the psoas muscle (Fig. 849). This fold has received the name of **suspensory ligament** of the ovary (or ovario-

pelvic ligament), and is a portion of the upper and outer part of the broad ligament of the uterus, which here contains between its two layers the ovarian vessels and nerves as they pass down into the pelvis to reach the hilum of the ovary. The vessels and nerves entering the ovary along its anterior border are enclosed in a sheath of peritoneum derived from the posterior layer of the broad ligament. In this way the ovary is connected along the whole length of its anterior border by a very short mesentery, or **mesovarium**, to the posterior aspect of the broad ligament (Fig. 850). The lower pole of the ovary is connected with the lateral angle of the uterus by a ligament called the **ligament of the ovary** (ligamentum ovarii proprium). This has the form of a rounded cord enclosed between the peritoneal folds of the broad ligament, and is attached to the uterus, behind and below the point of entrance of the Fallopian tube. It is chiefly composed of smooth muscle fibres continuous with those of the uterus. The upper pole of the ovary is usually directly connected with one of the largest of the fimbriæ surrounding the abdominal end of the Fallopian tube, which receives the name **ovarian fimbria** of the tube (Fig. 850).

**Descent of the Ovary.**—Like the testes, the ovaries at first lie in the abdominal cavity, and only later assume a lower position. At birth the ovary lies partly in the abdominal, and partly in the pelvic cavity; soon, however, it takes up a position entirely within the pelvis. As in the male a gubernaculum is present in the early stages of development. The ligament of the ovary represents the upper part of the gubernaculum which is developed within the plica testis inferior in the male, and the round ligament of the uterus represents the lower part, which is formed within the plica inguinalis (see p. 1168). It is a rare abnormality for the ovary, instead of entering the pelvis, to take a course similar to that of the testis, and pass through the inguinal canal into the tissue of the labium majus.

**Structure of the Ovary.**—The ovary is for the most part composed of a connective tissue stroma (stroma ovarii), richly supplied by blood-vessels and nerves. The stroma contains very numerous spindle-shaped connective tissue fibres, and some elastic tissue. The surface of the ovary is covered by a layer of epithelium, which is composed of columnar cubical cells, and is continuous with the epithelium of the peritoneum forming the mesovarium. The ovarian epithelium is a persistent portion of the germinal epithelium of the embryo which covers the genital ridges, and from which the ova and other cells of the Graafian follicles are derived. The position in which it becomes continuous with the peritoneum can usually be distinguished as a fine white line near the hilum of the ovary. Shining through the epithelium of the fresh ovary (except in old age), are usually to be seen a variable number of small vesicles—the **Graafian follicles** (folliculi oophori vesiculosi), in which the **ova** are contained. The number of follicles visible, and also the size which each follicle reaches before it ruptures and sheds its contents, is by no means constant. When a follicle ruptures and discharges the ovum its walls at first collapse, but later the cavity becomes filled with extravasated blood and cellular tissue of a yellowish colour. The resulting structure, called a **corpus luteum**, slowly degenerates unless impregnation has taken place, in which case it develops and becomes larger during pregnancy. As it atrophies the cells of the corpus luteum disappear, and the structure, losing its yellow colour, receives the name of **corpus albicans**. After a time the corpus albicans completely disappears. Owing to the periodic rupture of the Graafian follicles, the surface of the ovary, which is at first smooth and even, becomes in old age dimpled and puckered.

A section through the ovary, especially in young children, presents in its superficial part a somewhat granular appearance, which is due to the presence of enormous numbers of small follicles, or collections of epithelial cells, embedded in the connective tissue near the surface of the ovary. The larger follicles lie deeper in the stroma, but when they become fully developed they pass towards the surface, where the ripe follicles are often seen slightly projecting and ready to burst. In the deepest part of the ovary the blood-vessels are most numerous, and here also some smooth muscle fibres are to be found.

The ova and the other cells that compose the Graafian follicles are derived originally from the germinal epithelium which covers the developing ovary in the embryo. The epithelium, at first simple, grows down into the underlying tissue in the form of branching tube-like processes, or "egg tubes." This takes place during fœtal development, and the branching cellular processes so formed become broken up, within the stroma, into little nests or clumps of cells, each of which becomes a Graafian follicle. From the beginning some cells of the egg tubes are larger than the others; these become the future ova

while the cells round them become the investing cells of the follicle. The investing cells, at first flattened, form a single layer round each ovum. Later becoming columnar, as the follicle increases in size and sinks more deeply in the stroma, these cells divide in such a manner that the ovum becomes surrounded by a double layer of cells. Fluid—**liquor folliculi**—accumulates between the two cellular layers, except at one place where the inner cells surrounding the ovum remain attached to the outer layer or **stratum granulosum**. To the inner cellular mass enclosing the ovum (ovulum) the term **discus proligerus** (cumulus oophorus) is applied (Fig. 851). The ripe follicle contains a rela-

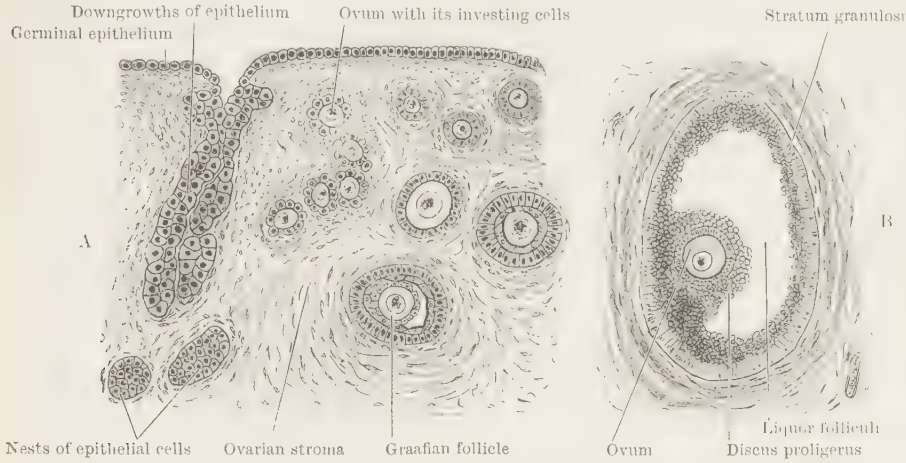

FIG. 851.—A. DIAGRAMMATIC REPRESENTATION OF THE MANNER IN WHICH THE GRAAFIAN FOLLICLES ARISE DURING THE DEVELOPMENT OF THE OVARY. B. DIAGRAM ILLUSTRATING THE STRUCTURE OF A RIPE GRAAFIAN FOLLICLE.

tively large amount of fluid, and the surrounding stroma becomes differentiated to form for each a **capsule** (theca folliculi). This capsule is composed of an inner more *vascular layer* (tunica interna), and an outer more *fibrous layer* (tunica externa). There is reason to believe that in the human embryo the formation of ova and follicles ceases at birth, and that the appearances which have led to the belief that they may originate during the first years of extrauterine life have been due to pathological conditions. In the young child there are enormous numbers of small follicles in the superficial parts of the ovary, but in old age none are found in this situation.

The appearance and structure of the ripe ova have been described on p. 10.

**Vessels and Nerves of the Ovary.**—The **ovarian arteries**, corresponding to the spermatic arteries of the male, are a pair of long slender vessels which spring from the anterior aspect of the aorta, below the level of origin of the renal vessels. Each gains the pelvis in the fold of peritoneum forming the suspensory ligament of the ovary, and enters the ovary at its anterior border or hilum. These ovarian arteries anastomose freely near the hilum with other vessels derived from the **uterine arteries**. The blood is returned by a series of communicating veins, similar to the **pampiniform plexus** in the male. The **nerves** of the ovary are derived chiefly from a plexus which accompanies the ovarian artery, and which is continuous above with the renal plexus. Other fibres are derived from the lower part of the aortic plexus, and join the plexus on the ovarian artery (plexus arteriæ ovaricæ). The afferent impulses from the ovary reach the central nervous system through the posterior root fibres of the tenth thoracic nerve. The **lymphatics** of the ovary join with those from the upper part of the uterus, and end in the lumbar lymphatic glands.

## THE FALLOPIAN TUBES.

The **Fallopian tubes** (tubæ uterinæ) are a pair of ducts or passages which convey the ova, discharged from the Graafian follicles of the ovaries, to the cavity of the uterus. Each tube is about four and a quarter inches in length, and opens at one end into the pelvic cavity near the ovary, and at the other end by a smaller opening into the lateral part of the uterine cavity. The tube is enclosed in a fold of peritoneum called the **mesosalphinx**, which is a portion of the broad ligament of the uterus.

The opening of the tube into the pelvic cavity—or **ostium abdominale**—is of small size, being only about 2 mm. in diameter when its walls are relaxed, and

much narrower when the muscular coat of the tube is contracted. This opening is placed at the bottom of a funnel-like expansion of the tube called the **infundibulum** (infundibulum tubæ uterinæ), the margins of which are produced into a number of irregular processes or **fimbriæ** (fimbriæ tubæ). The presence of these fimbriæ, many of which are branched or fringed, has given the name **fimbriated extremity** to this end of the Fallopian tube. The surface of the fimbriæ which looks into the cavity of the infundibulum is covered by a mucous membrane continuous with that lining the tube, while the outer surface is clothed by peritoneum. The mucous surfaces of the larger fimbriæ present ridges and grooves which are continued into the folds and furrows of the mucous coat of the tube. One of the fimbriæ, usually much larger than the rest, is connected either directly or indirectly with the upper or tubal pole of the ovary, and to it the name **ovarian fimbria** (fimbria ovarica) is applied. The part of the tube continuous with the infundibulum, and into which the ostium abdominale leads, is called the **ampulla** (ampulla tubæ uterinæ). This, the widest and longest portion of the Fallopian tube, is usually tortuous and of varying diameter, being in some places slightly constricted, and in others distended. The wide, thin-walled ampulla ends in the narrower, thicker-walled, and much shorter **isthmus** (isthmus tubæ uterinæ) which joins the lateral angle of the uterus. The last portion of the canal, or **pars uterina**, is embedded in the substance of the uterine wall, which it traverses to reach the cavity of the uterus (Fig. 852, B). The opening into the uterus (ostium uterinum tubæ) is smaller than the ostium abdominale, being about 1 mm. in diameter. The lumen of the canal gradually increases in width as it is traced outwards from the uterus towards the ovary.

**Course of the Fallopian Tube.** Traced from the lateral angle of the uterus the Fallopian tube is directed at first horizontally outwards towards the lower, or uterine, pole of the ovary. It then passes upwards in relation to the inner side of the anterior border of the ovary, until it reaches the upper or tubal pole, where, arching backwards, it descends along the posterior border, resting against the inner surface of the gland (Fig. 852). As the Fallopian tube describes this loop it often covers almost the entire inner surface of the ovary. The fimbriated end of the tube lies against the lower part of the inner surface of the ovary, and from it the ovarian fimbria passes upwards to gain attachment to the tubal pole.

The fimbriated end of the Fallopian tube lies in the abdominal cavity until the ovary in its descent has entered the pelvis.

**Structure of the Fallopian Tubes.**—The wall of each tube, which is surrounded by a covering of peritoneum (tunica serosa), is composed of a number of concentric layers, or coats. Immediately beneath the peritoneum is a layer of loose connective tissue in which lie many vessels and nerves (tunica adventitia). Beneath this is the **muscular coat** (tunica muscularis) composed of two strata of smooth muscle fibres,—a more superficial thin stratum of longitudinally arranged fibres (stratum longitudinale), and a deeper thicker layer, the fibres of which are circularly disposed (stratum circulare). Deeper is a **submucous layer** (tela submucosa), and then the lining membrane or **mucous coat** (tunica mucosa). In the part of the tube near the uterus the muscular layer is thicker than towards the other end, and in the isthmus it forms the chief part of the wall. The mucous membrane, on the contrary, is thickest towards the fimbriated end, and here it forms the chief part of the tube wall. The stratum of circular muscle fibres is especially well developed near the uterus. The mucous membrane is thrown into numerous longitudinal folds (plicæ tubariæ), which in the ampulla are exceedingly complex, the larger ones being beset on the surface by smaller folds. In transverse sections of this part of the tube the folds of the mucous membrane look like large branching processes projecting into, and almost completely filling up, the lumen of the tube. The mucous membrane is covered by a ciliated epithelium, the cilia of which tend to drive the contents of the tube towards the uterus. The epithelium is continuous with that of the uterus, and at the fimbriated end joins the peritoneum.

**Vessels and Nerves of the Fallopian Tube.**—The Fallopian tube receives its chief blood-supply from a branch of the **uterine artery** (ramus tubarius), but it also receives small branches derived from the **ovarian artery**. The veins of the tube pour their blood partly into the uterine and partly into the ovarian veins. The **nerves** are derived from the plexus that supplies the ovary, and also from the plexus in connexion with the uterus. The afferent fibres appear to belong to the eleventh and twelfth thoracic and the first lumbar nerves. The **lymphatics** join the lumbar group of glands.

**Epoophoron and Paroophoron.**—These are two rudimentary structures found between the layers of the broad ligament.

The **epoophoron**, or **parovarium** (sometimes called the organ of Rosenmüller), lies in the mesosalpinx between the Fallopian tube and the ovary. In the adult it consists of a number of small rudimentary blind tubules lined by an epithelium. One of these tubules, called the **duct of Gärtner** (ductus epoophori longitudinalis), lies close to, and runs nearly parallel with, the Fallopian tube. It is joined by a number of the other tubules (ductuli transversi) which enter it at right angles from the neighbourhood of the ovary. The duct of Gärtner is a persistent portion of the Wolffian duct, and represents the canal of the epididymis in the male, while the tubules which join it are derived from the mesonephros and represent the vasa efferentia and coni vasculosi of the testis (and probably also the ductuli aberrantes of the canal of the epididymis). The epoophoron is best seen by holding up to the light the part of the broad ligament in which it lies.

One or more small pedunculated cystic structures, called **hydatids of Morgagni** (appendices vesiculosi), are often seen near the infundibulum of the Fallopian tube. These are usually supposed to represent portions of the upper end of the Wolffian duct.

The **paroophoron** is a collection of rudimentary tubules also enclosed by the layers of the mesosalpinx, but lying nearer the uterus than the epoophoron. These very rudimentary tubules represent the paradidymis or organ of Giraldés, in the male, and are derived from the part of the mesonephros which lies nearer the caudal end of the body of the embryo. Though sometimes visible in the child at birth, the paroopheron in the adult can only be made out with the aid of a lens.

## THE UTERUS.

The **uterus** or womb is a hollow, thick-walled, muscular organ placed within the pelvis between the bladder in front and the rectum behind. The ova discharged from the ovary enter the uterus through the Fallopian tubes, and, if fertilisation has taken place, undergo their development within it. In form the uterus is somewhat pear-shaped, the wide upper end of the organ projecting freely upwards and forwards into the pelvic cavity, while the lower more constricted part is connected with the vagina. The usual length of the adult uterus (when non-pregnant) is three inches, its greatest breadth is nearly two inches, and its maximum thickness is about one inch.

In the description of the uterus we distinguish between an upper larger portion, somewhat flattened from before backwards, composed of fundus and body, and a lower more cylindrical part called the cervix (Fig. 852). The part of the uterus that lies above the level of a line joining the points of entrance of the Fallopian tubes is called the **fundus** (fundus uteri). The fundus is convex from before backwards and from side to side, its anterior and posterior aspects being directly continuous with the anterior and posterior surfaces of the body of the organ. The **body** of the uterus (corpus uteri), when seen from in front or from behind, has a somewhat triangular outline, and lies below the fundus, with which it is continuous. The base of the triangle is directed upwards and is formed by a line joining the lateral angles of the uterus, or points of entrance of the Fallopian tubes, and the sides of the triangle correspond to the lateral borders of the uterus, which extend on each side from the lateral angle to the cervix. The *lateral border* (margo lateralis) separates on each side the *anterior surface* (facies vesicalis) from the *posterior surface* (facies intestinalis) of the body. Both these surfaces are rounded, but the posterior is much the more convex. The anterior surface rests against the upper aspect of the bladder, from which usually it is separated only by the layers of peritoneum forming the utero-vesical pouch. The posterior surface forms the chief part of the anterior wall of the deep recess situated between the uterus and rectum, and is usually in contact with some part of the small intestine or the pelvic colon.

The broad ligament passes outwards on each side of the uterus from the lateral border of the organ.

The **neck**, or **cervix uteri**, is cylindrical, and at its commencement it is sometimes marked off from the body by a slight constriction. Its length is about one inch, and its lower end, tapering somewhat, enters the upper part of the vagina. The cervix is attached to the margin of the opening in the vaginal wall, through which it passes, and in this way a **supravaginal portion** (portio supravaginalis) is marked off from a **vaginal portion** (portio vaginalis) of the cervix. In the vaginal portion of the cervix there is an opening — the **external os uteri** (orificium externum uteri)—through which the cavity of the uterus communicates with that of the vagina. In the uterus which has never been pregnant this opening is nearly circular, but in women who have borne children it is usually a transverse slit with a somewhat irregular outline. In front of and behind this opening the cervix forms two lips, an *anterior* and a *posterior* (labium anterius et labium posterius). The anterior lip is thicker, and slightly more rounded; it is placed upon a lower level than the posterior lip, which is slightly longer and thinner The cervix enters the vagina through the upper part of its anterior wall in such a manner that the external os uteri is directed backwards and downwards against the upper part of the posterior vaginal wall (Fig. 853).

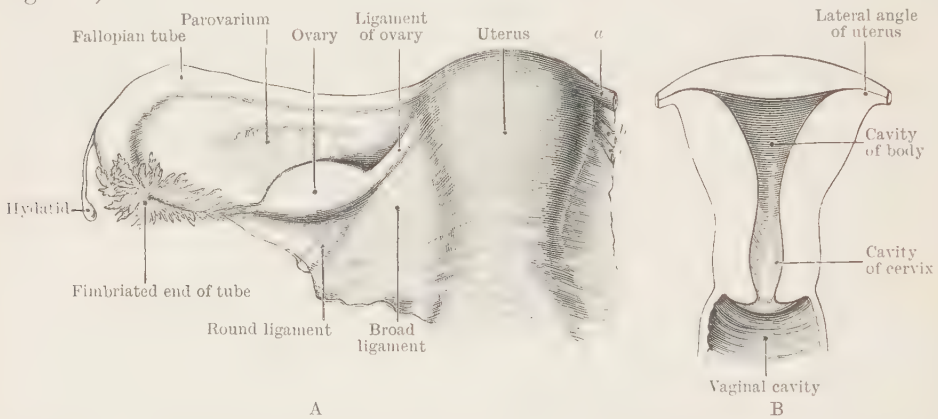

FIG. 852.—A. THE UTERUS AND BROAD LIGAMENT SEEN FROM BEHIND (the broad ligament has been spread out).

*a*, *b*, and *c*, the isthmus tubæ, the ligament of the ovary, and the round ligament of the right side cut short.

B. DIAGRAMMATIC REPRESENTATION OF THE UTERINE CAVITY OPENED UP FROM IN FRONT.

**Cavity of the Uterus.**— In comparison with the size of the organ, the cavity of the uterus (cavum uteri) is of small size owing to the great thickness of the uterine wall. In the body, or corpus uteri, the cavity is merely a narrow chink between the anterior and posterior walls, which are almost in contact (Fig. 853). When, however, the organ is opened from above downwards in coronal section the cavity of the body has a triangular outline (Fig. 852). The base of the triangle is directed upwards, and corresponds to a line drawn between the openings of the Fallopian tubes, while the apex is directed downwards towards the cervix. The sides of the triangle are convex inwards towards the cavity. The cavity of the body becomes continuous with that of the neck, or cervix, by an opening called the **internal os uteri** (orificium internum uteri), which is a little smaller and more circular than the external os uteri. The cavity of the cervix, or **cervical canal** (canalis cervicis uteri), extends from the internal os uteri, where it joins the cavity of the body, to the external os uteri, where it opens into the vagina. It is a somewhat spindle-shaped passage, which is narrower above and below than in its middle part; also sections show that its antero-posterior diameter is shorter than its transverse one, owing to an approximation of its anterior and posterior walls. In the body of the uterus the walls of the cavity are smooth and even, but in the cervical canal the mucous membrane forms a remarkable series of folds, called the **arbor vitæ uterinæ** or **plicæ palmatæ**. These consist of an anterior and a posterior longitudinally, directed fold or ridge, from which a large number of secondary folds, or rugæ, branch off obliquely upwards and outwards (Fig. 852).

**Connexions of the Uterus and its Relations to the Peritoneum.**—In addition to the Fallopian tubes at its upper lateral angles, and the vagina below, the uterus possesses other important connexions. Some of these are simply peritoneal folds passing from the uterus to neighbouring structures; others contain fibrous connective tissue, or smooth muscle fibres.

The peritoneum covering the fundus of the uterus is continued down over the anterior surface as far as the junction of the body and cervix, where it leaves the uterus to be reflected on to the bladder, forming the **utero-vesical fold**, or "anterior ligament of the uterus." The peritoneal recess between the bladder and the uterus is called the utero-vesical pouch (excavatio vesico-uterina). Below the level of the floor of this pouch the anterior aspect of the cervix is connected by loose tissue with the posterior, or basal, part of the bladder. Posteriorly the peritoneum covers the whole of the uterus, except the small portion of the cervix which projects into the upper part of the vagina. The peritoneum covering the posterior surface of the uterus is continued to such a depth that it invests a small portion of the upper part of the posterior wall of the vagina before it is reflected on to the rectum, to form the **recto-vaginal fold** (Fig. 853). The deep pouch between the uterus and vagina in front and the rectum behind is called the **pouch of Douglas** (excavatio recto-uterina or recto-genital pouch), and its entrance is bounded on each side by a crescentic peritoneal fold, which passes from the posterior surface of the cervix uteri to the posterior wall of the pelvis, and ends near the side of the rectum. These crescentic folds are called the **recto-uterine folds** (plicæ recto-uterinæ, recto-genital folds), or **folds of Douglas**, and each contains between its layers a considerable amount of fibrous and smooth muscular tissue. Some of these fibres, which are continuous with the uterine wall, pass backwards to reach the rectum and constitute the **recto-uterine muscle** (musculus recto-uterinus); others, gaining an attachment to the front of the sacrum, form the **utero-sacral ligament**. In many cases the recto-uterine folds become continuous with one another across the middle line behind the cervix uteri, and form, in this position, a transverse ridge termed the **torus uterinus**. The pouch of Douglas, or recto-genital pouch of the female, represents the recto-vesical, or recto-genital pouch of the male, and the folds which bound it laterally, namely, the recto-uterine folds, correspond to the sacro-genital folds (sometimes called posterior false ligaments of the bladder) in the male sex. The peritoneum of the anterior and posterior surfaces, leaving the uterus along each lateral border to reach the side wall of the pelvis, forms the broad ligament of the uterus.

The **broad ligament** (ligamentum latum uteri) is a wide peritoneal fold which passes from the lateral border of the uterus to the pelvic wall, and contains between its layers several important structures (Fig. 852). The plane of the inner part of the ligament is determined by the position of the uterus. When the uterus is normally placed, the ligament has an anterior surface which looks downwards as well as forwards, and a posterior one which looks upwards and backwards. Near its attachment to the pelvis the ligament is placed more vertically. The free edge of the ligament contains the Fallopian tube, and follows the course pursued by that structure. Thus, in the undisturbed condition of parts, it at first passes horizontally outwards towards the lower end of the ovary, where it ascends to arch over the upper pole of the ovary on its inner side. Owing to the course pursued by the Fallopian tube round the ovary, the broad ligament forms a kind of curtain over the gland, and the ovary lies in a little pocket formed by the broad ligament, to which the name of **bursa ovarii** is applied (Figs. 848 and 849). This bursa ovarii is not to be confused with the fossa ovarica, or depression on the side wall of the pelvis, against which the ovary is usually placed.

The various structures in connexion with the broad ligament are most easily demonstrated when the ligament is spread out as flat as possible.

The ovary is connected with the posterior layer of the broad ligament by a very short mesentery, called the **mesovarium**, which, passing to the hilum, encloses the ovarian vessels and nerves as they reach the ovary. The part of the broad ligament which slings the Fallopian tube is called the **mesosalpinx**. When the ligament is spread out, the mesosalpinx has the form of a narrow triangle, the

apex of which is at the lateral angle of the uterus, while the upper side is formed by the Fallopian tube, and the lower one by the ligament of the ovary and the ovary itself. The narrow base of the triangle is directed outwards. Between the layers of this part of the broad ligament are situated the parovarium (epoophoron) and the paroophoron (Fig. 852). The part of the broad ligament below the level of the mesosalpinx is termed **mesometrium**, and contains, especially in its lower part, a considerable amount of fatty connective tissue (parametrium) and unstriped muscle fibres. The ureter and the uterine vessels lie in the lowest part of the broad ligament where it joins the pelvic floor.

The highest part of the attached lateral portion of the broad ligament forms the suspensory ligament of the ovary and contains between its layers the ovarian vessels and nerves, as they enter or leave the pelvis.

The **ligament of the ovary** (ligamentum ovarii proprium) is a rounded fibrous cord, of about one to one and a half inches in length, which is attached by its outer end to the lower pole of the ovary, and by its inner end to the lateral angle of the uterus immediately below and behind the entrance of the Fallopian tube. This ligament, which is largely composed of unstriped muscle fibres continuous with those of the uterus, is enclosed in a slight fold derived from the posterior layer of the broad ligament.

The ligament of the ovary represents the upper portion of the gubernaculum which appears in the embryo.

The **round ligament** of the uterus (ligamentum teres uteri) is a narrow flat band attached to the uterus just in front of and a little below the opening of the Fallopian tube. Near the uterus it contains numerous smooth muscle fibres, which are continuous with those of the uterus; further on it is chiefly composed of fibrous connective tissue. Lying in the anterior part of the broad ligament, it reaches the pelvic wall, and is then directed forwards and slightly upwards to cross the obliterated hypogastric artery and the pelvic brim. After it has reached the pelvic wall its course is comparable to that of the vas deferens in the male, and, like the latter, it leaves the abdomen to traverse the inguinal canal (Figs. 845 and 848). It finally ends in the subcutaneous tissue and skin of the labium majus. Its terminal part is composed of connective tissue only.

In some cases a small diverticulum of the peritoneal cavity can be traced accompanying the round ligament through the abdominal wall. This is called the **canal of Nuck** (processus vaginalis peritonæi), and corresponds to the processus vaginalis of the male (p. 1167).

The round ligament of the uterus represents the lower portion of the gubernaculum testis which appears in the male embryo (see pp. 1168 and 1184).

**Position and Relations of the Uterus.**—The position occupied by the uterus in the pelvis is not always the same, but varies with the conditions of the neighbouring organs. The lower cervical part is, however, much more firmly fixed in place than the body and fundus, which possess a considerable amount of mobility. Usually the level of the external os uteri will be found to correspond to that of a horizontal plane passing through the upper margin of the symphysis pubis. The uterus rarely lies exactly in the mesial plane of the body, but usually bends to one or other side, most frequently towards the right. The anterior surface of the uterus rests against the bladder, and follows the rising or falling of its superior wall as that organ becomes filled or emptied. When the bladder is empty the long axis of the uterus points forwards and upwards, and the organ is said to be in an *anteverted* position. Also the long axis of the uterus is bent on itself where the body joins the cervix, and so the organ is said to be *anteflexed*. The anteflexion is due to the fact that the more rigid cervix is fixed, while the movable upper part of the uterus sinks forwards, following the bladder wall. With the empty condition of the bladder the angle formed between the long axis of the uterus and that of the vagina is about a right angle. When the bladder becomes filled, the anteversion and anteflexion of the uterus become less marked, owing to the body and fundus being pushed backwards. Finally, if the rectum be empty and the bladder very much distended, the uterus is pushed so much backwards that the long axis of the organ may nearly correspond to that of the vagina. The uterus is then said to be

*retroverted*. Superiorly a part of the peritoneal cavity intervenes between the anterior surface of the uterus and the bladder, but lower down the two organs are separated merely by a small quantity of connective tissue. The posterior surface of the uterus looks into the pouch of Douglas, and is usually, like the fundus, in relation to some loops of intestine. Laterally the uterus is related to the broad ligaments. The terminal parts of the ureters pass downwards, inwards, and a little forwards on each side of the cervix, but are separated from it by an interval of about three-quarters of an inch. The lowest part of the cervix is, as we have seen, enclosed within the cavity of the vagina.

On each side of the cervix uteri and upper part of the vagina there is an interval in which lie numerous large vessels. These are surrounded by loose fatty tissue, which is continued upwards for a considerable distance between the layers of the broad ligament. This loose tissue, which is of surgical importance, has received the name **parametrium**.

**Structure of the Uterus.**—The thick uterine wall is composed of three chief layers, which are termed respectively the serous, the muscular, and the mucous coats.

The **serous coat** or **perimetrium** (tunica serosa) is derived from the peritoneum, and covers the whole organ except the anterior surface of the cervix, and the part of the cervix which projects into the vagina. At the lateral borders it is continued into the broad ligaments. Over the fundus and body of the uterus the serous coat is very firmly adherent to the deeper layers, and cannot be easily peeled off without tearing either it or the underlying muscular tissue. Near the lateral borders the peritoneum is less firmly attached, and over the posterior aspect of the cervix it may readily be stripped off without injury to the underlying structures.

The **muscular coat** (tunica muscularis) is composed of unstriped fibres, and forms the chief part of the uterine wall. Inferiorly the muscular coat of the uterus becomes continuous with that of the vagina. The more superficial layer of the muscular coat sends prolongations into the recto-uterine folds, into the round and broad ligaments of the uterus, and into the ovarian ligaments. Other fibres join the walls of the Fallopian tubes. The main branches of the blood-vessels and nerves of the uterus lie among the muscle fibres. In the deeper layers of the muscular coat a considerable amount of connective tissue and some elastic fibres are to be found. The muscular coat of the cervix (tunica muscularis cervicis) contains more connective and elastic tissue than that of the body, and hence the greater firmness and rigidity of the cervical part of the uterus.

The deeper and thicker part of the muscular tissue of the uterus is considered by some anatomists to represent a **muscularis mucosæ**, and is therefore described as part of the mucous coat. The deep and superficial portions of the muscular coat are, however, quite continuous, and there is no representative of a submucous vascular layer of tissue such as in the alimentary canal separates the muscular coat from the muscularis mucosæ. In the uterus the blood-vessels lie in the muscular coat.

The **mucous coat** (tunica mucosa) in the body of the uterus is smooth and soft, and covered by columnar ciliated epithelium. Simple tubular glands (glandulæ uterinæ), also lined by a ciliated epithelium, are present in the mucous membrane, and penetrate in their deeper parts into the muscular coat. In the cervix of the uterus the mucous coat is firmer and more fibrous than in the body, and its surface is not smooth, but presents a number of peculiarly disposed ridges, which have been already described. Like the mucous membrane of the body of the uterus, that of the cervix is covered by a ciliated epithelium which passes into squamous epithelium just inside the external os uteri. The cervix uteri possesses, in addition to unbranched tubular glands, resembling those present in the body, numerous somewhat branched glands (glandulæ cervicales uteri). Both kinds of glands are lined by ciliated epithelium. In many cases little clear retention cysts, **ovules of Naboth**, are to be seen in the cervical mucous membrane, which arise as a result of obstruction at the mouths of the glands.

**Difference in the Uterus at Different Ages.**—At birth the cervix uteri is relatively larger than in the adult organ, and its cavity is not distinctly marked off from the interior of the body by an internal os uteri. At this time also the arbor vitæ extends throughout the whole length of the uterus. The organ grows slowly until just before puberty, when its growth is rapid for a time. As the body increases in size the mucous membrane becomes smooth and the arbor vitæ becomes restricted to the cervix. In women who have borne children the cavity

remains permanently somewhat wider and larger than in cases where the uterus has never been pregnant.

In old age the uterine wall becomes harder and has a paler colour than it possesses in the young subject.

**Variations.**—In rare cases the uterus may be divided by a septum into two distinct cavities, or its lateral angles may be produced into straight or curved processes, called "horns" or cornua. The latter abnormality recalls the appearance of the bicornuate uteri of some animals. Both the above conditions arise from an arrest in the fusion of the two separate tubes—the Müllerian ducts—which normally unite to form the uterus.

**Periodic Changes in the Uterine Wall.**—At each menstrual period a remarkable series of changes occurs which results in a periodic shedding of the superficial parts of the uterine mucous membrane. For a few days before menstruation begins, the mucous membrane gradually thickens and becomes more vascular, while at the same time its surface becomes uneven. Soon the superficial parts of the mucous membrane disintegrate and hæmorrhage takes place from the small superficial blood-vessels. In this way a hæmorrhagic discharge is caused, and the superficial parts of the uterine mucous membrane are shed at each period. When menstruation is over the mucous membrane is rapidly regenerated.

**Pregnant Uterus.**—The pregnant uterus increases rapidly in size and weight, so that from being three inches in length and one ounce in weight, it becomes by the eighth month about seven or eight inches in length and sometimes as much as two pounds in weight. In shape the uterus is now oval or rounded, with a thick wall composed chiefly of muscle fibres arranged in distinct layers. The rounded fundus is very prominent. The round ligaments are stronger and better marked, and the layers of the broad ligament become separated in their inner parts by the growth of the uterus between them. The blood-vessels, especially the arteries, are very large and tortuous. The changes which occur in the mucous membrane of the pregnant uterus are intimately connected with the manner in which the developing fœtus receives its nutrition, and have been noticed on p. 53.

**Vessels and Nerves of the Uterus.**—The uterus receives its arterial supply from the **uterine arteries**, which are branches of the internal iliac arteries, and also from the **ovarian arteries**, branches of the aorta. The vessels derived from these two sources communicate freely with one another. Each uterine artery, reaching the side of the lower part of the uterus, divides into a large branch which passes upwards to supply the body and fundus, and a much smaller branch which passes downwards to supply the cervix. The vessels distributed to the body and fundus have an exceedingly tortuous course. The branches of the uterine artery, having entered the muscular coat, break up within its deeper layers into smaller twigs which supply the muscular tissue and the mucous coat. The small uterine branch from the ovarian artery reaches the uterus in the region of the lateral angle. During pregnancy the arteries become enormously enlarged.

The thin-walled **veins** form a plexus which pours its blood into the tributaries of the internal iliac vein.

The **nerves** of the uterus are derived chiefly from a plexus placed in the neighbourhood of the cervix uteri, to which the term **cervical ganglion** or **plexus utero-vaginalis** is applied. Superiorly this plexus is continuous with the hypogastric plexus, but it also receives fibres from the third and fourth sacral nerves. In addition to fibres from the plexus utero-vaginalis, the uterus receives fibres directly from the **hypogastric plexus**, and also from the **vesical plexus**.

Clinical observations indicate that afferent impulses reach the central nervous system from the uterus through the posterior roots of the tenth, eleventh, and twelfth thoracic nerves, the first lumbar, and the second, third, and fourth sacral nerves.

The numerous **lymphatic vessels** coming from the body of the uterus join those from the ovary and end for the most part in the lumbar lymphatic glands. Along the course of the round ligament of the uterus there are a few lymphatic vessels which establish a connexion between the lymphatic network surrounding the uterus and the inguinal lymphatic glands. The lymphatics from the cervix uteri end in the gland placed near the bifurcation of the common iliac artery.

## THE VAGINA.

The **vagina** is a passage about three inches in length, open at its lower end, and communicating above with the cavity of the uterus. The passage is directed downwards and forwards, describing a slight curve which is convex backwards. The axis of the vagina forms with that of the uterus an angle which is

open forwards. This angle is usually somewhat greater than a right angle, but varies with the condition of the neighbouring viscera (p. 1190). The vagina is wider in its middle part than it is at either end, and normally its anterior and posterior walls are in contact. In transverse section the lower part is usually an H-shaped cleft, the middle part a simple transverse slit, while the lumen of the upper portion, into which the cervix uteri projects, is more open. The lower part of the cervix uteri has the appearance of entering the vagina through the upper portion of its anterior wall (Fig. 853). As more of the posterior than of the anterior part of the cervix

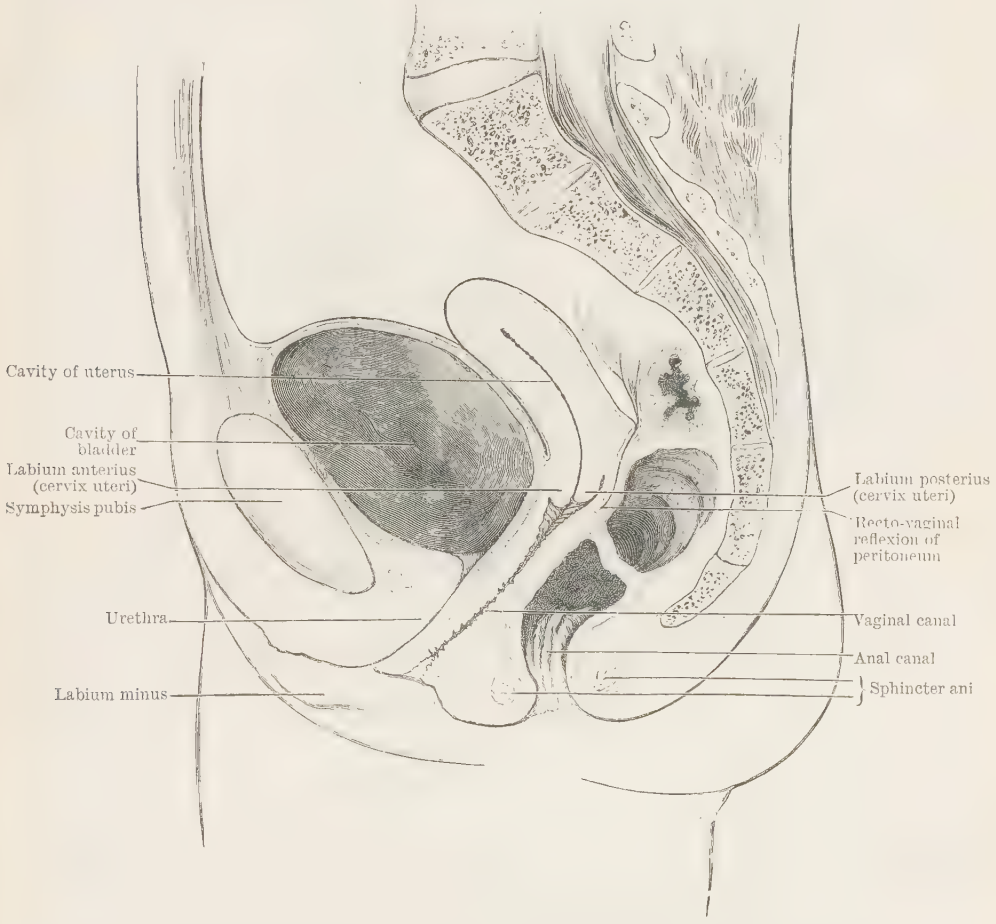

Fig. 853.—Mesial Section of the Pelvis in an Adult Female.

The cavity of the uterus is indicated diagrammatically. From a specimen in the Anatomical Department, Trinity College, Dublin.

projects into the vagina, a deeper recess is formed between the vaginal wall and the cervix behind, than in front or laterally. The term **anterior fornix** is often applied to the angle or recess in front, **posterior fornix** to the deeper angle behind, and **lateral fornix** to the recess on each side of the cervix uteri, between it and the wall of the vagina. The *anterior* vaginal wall (paries anterior) is shorter than the *posterior* (paries posterior), the former being about three inches in length, the latter about three and a half inches. At its lower end the vagina opens into the urinogenital cleft, the opening being situated behind the orifice of the urethra and the clitoris, and between the labia minora. The opening is partly closed in the virgin by a thin crescentic or annular fold, called the **hymen**, torn fragments of which persist round the opening, as the **carunculæ hymenales**, after the fold itself has been ruptured.

**Relations of the Vagina.**—The anterior wall of the vagina in its upper part

lies against the base of the bladder, but is separated from it by loose connective tissue. Lower down, the anterior wall in the mesial line is intimately connected with the urethra (Fig. 853). Near the middle line the posterior wall, in its upper portion, is covered for a distance of about a quarter of an inch by the peritoneum, which here forms the anterior boundary of the deepest part of the pouch of

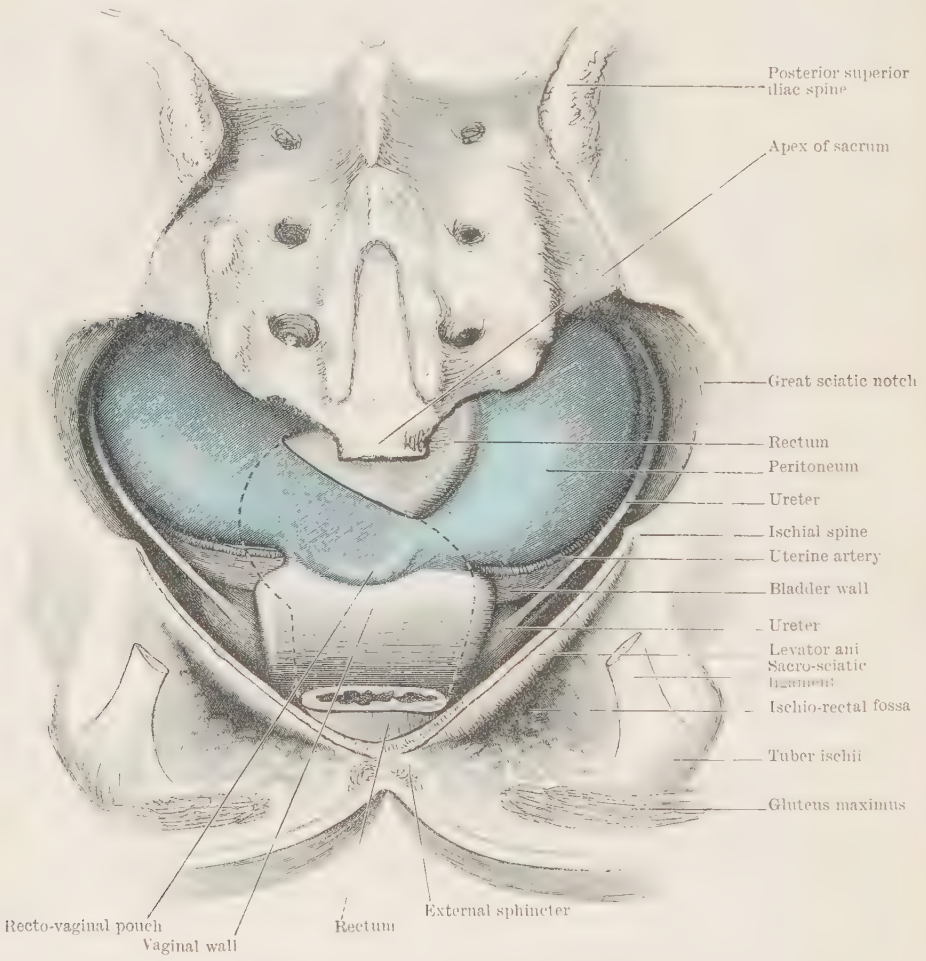

FIG. 854.—THE VAGINA, THE BASE OF BLADDER, AND THE RECTO-VAGINAL POUCH OF PERITONEUM, seen from behind.

The coccyx and the sacro-sciatic ligaments, together with the muscles attached to them, have been removed. The levatores ani have been separated along the median raphe, and drawn outwards. A considerable portion of the rectum has been removed, but the position which it occupied is indicated by the dotted lines. The peritoneum is indicated by a blue colour. The recto-vaginal pouch is probably not quite so deep as usual.

Douglas. The depth to which the peritoneum of this pouch descends practically corresponds to the level of the ischial spines. Lower down, the posterior wall lies close against the rectum, from which it is separated by a layer of the pelvic fascia. As, however, the orifice of the vagina is approached, the rectum and vagina become separated by a considerable interval, which is occupied by a mass of fibrous and fatty tissue, often called the "perineum" or "perineal body." At the sides the vagina is supported by the levatores ani muscles. The terminal part of the ureter lies not far from the side wall of the upper part of the vagina, as it passes from above and behind downwards, inwards, and a little forwards to reach the bladder. Near its termination the vagina pierces the triangular ligament, and is related laterally to the bulbus vestibuli, the gland of Bartholin, and the sphincter vaginæ muscle.

**Structure of the Vagina.**—The vaginal wall has a distinct **muscular coat** (tunica muscularis), composed of unstriped muscle fibres, most of which are longitudinally disposed. Towards the lower end of the passage circularly-disposed bundles of striped muscle fibres, some of which are continuous with those forming a part of the urethral wall, are found in the muscular coat. The thick **mucous membrane** (tunica mucosa), which has a stratified scaly epithelium, is corrugated, and presents a number of transverse ridges or elevations called **rugæ vaginales**. In addition to these transverse rugæ, a slightly marked longitudinal ridge, or column, is to be seen on the anterior and on the posterior wall of the vagina. These receive the name **columnæ rugarum**, and, like the transverse rugæ, are best seen in young subjects and in the lower part of the vagina. The urethral canal lies in close relationship to the anterior column of the vagina in its lower part, and hence this portion of the anterior column is sometimes called the **carina urethralis** (Figs. 820, B, and 853).

Within the mucous coat are to be found small collections, or nodules, of lymphoid tissue.

The vaginal wall is surrounded by a layer of loose vascular connective tissue containing numerous large communicating veins.

**Variation.**—In rare cases the vagina has been found divided by an incomplete septum into two passages. Such abnormality is due to an incomplete fusion of the lower portions of the Müllerian ducts from which the vagina is developed in the embryo.

**Vessels and Nerves of the Vagina.**—The blood-supply of the vagina is for the most part derived from branches of the **vesico-vaginal artery**, the vaginal branch of the **uterine artery**, the vaginal branches of the **middle hæmorrhoidal artery**, and from the branches of the **internal pudic**. The **veins** form a plexus surrounding the vaginal wall, and drain their blood into the tributaries of the internal iliac. The **lymphatics** from the upper part of the vagina join the internal iliac group of glands, while those from the lower part end in the superficial inguinal glands. The **nerves** of the vagina are derived from the **plexus utero-vaginalis**, and from the **plexus vesicalis**. Other fibres are derived directly from the **third** and **fourth sacral nerves**.

## THE FEMALE EXTERNAL GENITAL ORGANS.

The term **vulva**, or **pudendum** (pudendum muliebre), is often applied collectively to the female external genital organs, *i.e.* to the labia majora and the structures which lie between them.

**Labia Majora.**—The labia majora represent the scrotum in the male, and form the largest part of the female external genital organs. They form the lateral boundaries of the **urinogenital cleft** (rima pudendi), into which the urethra and vagina open. Each labium is a prominent rounded fold of skin, narrow behind where it approaches the anus, but increasing in size as it passes forwards and upwards to end in a median elevation, the **mons pubis** or **Veneris**. The mons Veneris, also called the **anterior commissure** (commissura labiorum anterior), lies over the symphysis pubis, and, like the labia majora, it is composed chiefly of fatty and areolar tissue, and is covered by hair. The outer convex surface of each labium majus is covered by skin containing numerous sebaceous glands and resembling that of the scrotum in the male, but the inner flatter surface is smooth, and presents a more delicate integumentary covering. In some cases the posterior narrow ends of the labia majora are connected across the middle line in front of the anus by a slight transverse fold—the **posterior commissure** (commissura labiorum posterior).

Usually, especially in young subjects, the labia majora are the only visible parts of the external genital organs, since they are in contact with one another, and completely enclose the structures within the urinogenital cleft.

The round ligament of the uterus ends in the fatty tissue of the labium majus. The superficial subcutaneous tissue resembles that of the scrotum, but contains no muscular fibres. The nerve supply corresponds with that of the scrotum, the anterior part of each labium being supplied by the branches of the **ilio-inguinal nerve**, and the posterior part by branches from the **internal pudic**, and by the perineal branch of the small sciatic nerve. The blood-vessels of the labia majora are derived from the **superficial pudic arteries** and from the perineal branches of the **internal pudic vessels**.

**Labia Minora.**—The labia minora, or nymphæ (labia minora pudendi), are a pair of much smaller and narrower longitudinal folds, usually completely

enclosed within the cleft between the labia majora. Diminishing in size, and becoming less marked in their posterior parts, the labia minora end by gradually joining the inner surfaces of the labia majora. In the young subject, a slightly raised transverse fold is usually seen connecting the posterior ends of the labia minora; to this fold the term **frenulum** (frenulum labiorum pudendi), or **fourchette**, is applied. Traced forwards, each labium minus divides into two portions, an outer and an inner. The outer portions of the two labia unite over the glans clitoridis, and form a fold or covering for it, called the **præputium clitoridis**. The inner portions, uniting at an acute angle, join the glans and form the **frenulum clitoridis**. The skin of the labia minora resembles the integument on the inner or deep surface of the labia majora, being smooth, moist, and pink in colour. The inner surfaces of the labia minora are in contact with one another; their outer surfaces are applied against the inner aspects of the labia majora.

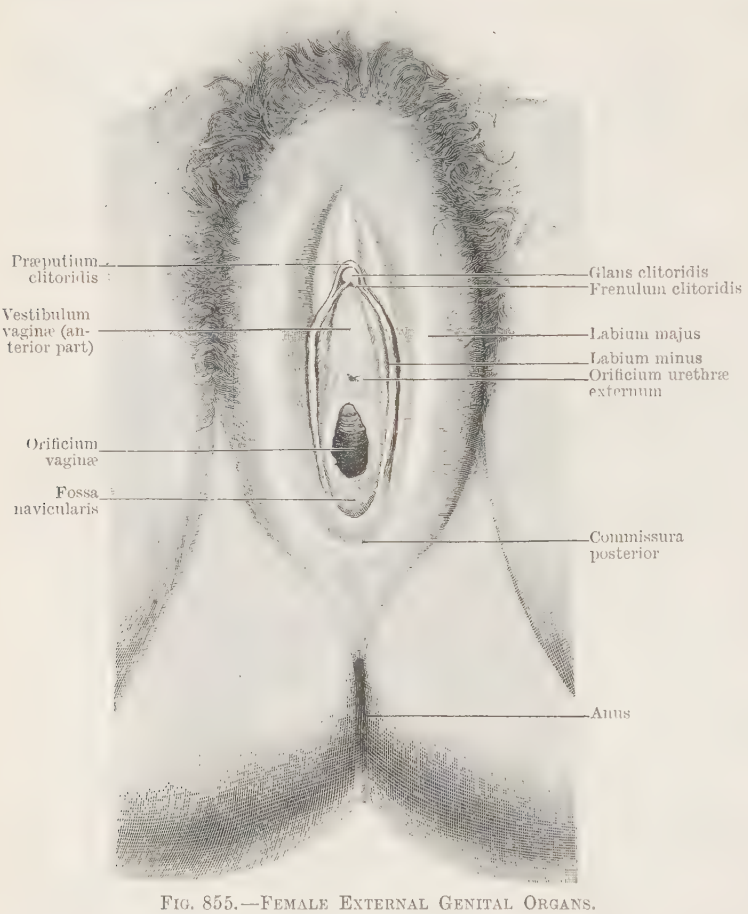

FIG. 855.—FEMALE EXTERNAL GENITAL ORGANS.

The fourchette is seen stretching across behind the fossa navicularis and in front of the posterior commissure. The ducts of Bartholin's glands open in the intervals between the vaginal orifice and the inner edges of the labia minora.

The openings of the urethra and vagina are placed in the middle line, in the interval between the labia minora, which must be separated to bring them into view.

The **vestibule** (vestibulum vaginæ) is the name applied to the cleft that lies between the labia minora and behind the glans clitoridis. In its floor are the openings of the urethra, the vagina and the minute ducts of Bartholin's glands.

The **fossa navicularis** is the part of the vestibule placed behind the vaginal opening and in front of the fourchette.

The **external urethral orifice** lies immediately in front of that of the vagina, and is about one inch behind the glans clitoridis. The opening has the appearance of a vertical slit, or of an inverted V-shaped cleft, the slightly prominent margins of which are in contact. On each side of the urethral orifice there may sometimes be seen the minute opening of the para-urethral duct (see page 1158).

The **vaginal opening** (orificium vaginæ) lies further back and below the orifice of the urethra. The appearance of the opening varies with the condition of the **hymen**—a membrane which in the young subject partly closes the aperture. When the hymen is intact the opening is small, and is only seen when the membrane is

put on the stretch. When the hymen has been ruptured the opening is much larger, and round its margins are often seen small projections **carunculæ hymenales**—which are to be looked upon as persistent portions of the hymen.

The **hymen** is a thin membranous fold, partially closing the lower end of the vagina, and usually perforated somewhat in front of its middle point. The position of the opening gives the fold, when stretched, a crescentic appearance. The opening in the hymen is sometimes cleanly cut, sometimes fringed. The membrane is not stretched tightly across the lower end of the vagina, but is so ample that it projects downwards into the urinogenital fissure, and the parts of its upper surface are in contact with one another on each side of the opening. The opening is thus a mesial slit whose margins are normally in contact. The upper surface of the hymen is directly continuous with the vaginal wall, and on it are to be seen slight ridges continuous with the vaginal rugæ.

Developmentally the hymen appears to be a portion of the vagina.

On each side of the vaginal opening, and close against the inner side of the attached margin of the labium minus, is the minute opening of the duct of Bartholin's gland. This is usually just large enough to be visible to the unaided eye.

Numerous minute mucous glands (glandulæ vestibuli minores) open on the surface of the mucous membrane of the vestibule, between the urethral and vaginal orifices. The opening of the ductus para-urethralis at the side of the urethral orifice has been already noted, pp. 1196 and 1158.

**Clitoris.**—The clitoris is the morphological equivalent of the penis, and is composed of a body and two crura. Upon the summit of the body is a minute glans. Unlike the penis, the clitoris is not traversed by the urethra.

The **body of the clitoris** (corpus clitoridis) is composed for the most part of erectile tissue resembling that of the penis in the male. It is about an inch or an inch and a half in length, and is bent upon itself, forming an angle open downwards. The body of the clitoris tapers towards its distal end, which is covered by the glans clitoridis. The organ is enclosed in a dense fibrous coat, and is divided by an incomplete **septum** (septum corporum cavernosorum) into two symmetrical and somewhat cylindrical portions, the **corpora cavernosa clitoridis**. These represent the corpora cavernosa of the male, and diverge from one another at the root of the clitoris to form the crura clitoridis. A **suspensory ligament** (ligamentum suspensorium clitoridis) passes from the fibrous coat of the body of the clitoris to the symphysis pubis.

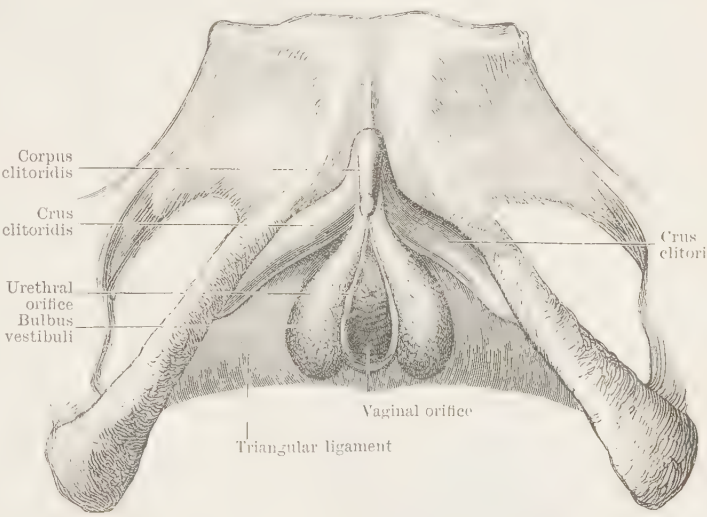

FIG. 856.—DISSECTION OF THE FEMALE EXTERNAL GENITAL ORGANS.
The suspensory ligament is seen passing upwards towards the symphysis pubis.

The **glans clitoridis** is a small mass of erectile tissue which is fitted over the pointed end of the body. It possesses, like the glans penis which it represents, a very sensitive epithelium. The **prepuce**, or fold of skin which covers it, and the **frenulum** which is attached to it inferiorly, are continuous with the labia minora (Fig. 855).

The **crura clitoridis** diverge from the body posteriorly, and are attached to the sides of the pubic arch. Each is continuous with one of the corpora cavernosa, and

has a firm fibrous sheath, which is covered by the corresponding ischio-cavernosus or erector clitoridis muscle. In structure the crura and body of the clitoris resemble the corpora cavernosa penis, while the glans more closely resembles the bulbus vestibuli, with which it is continuous through a structure known as the pars intermedia.

In the seal and some other animals, a bone, which represents the os penis of the male, is developed in the septum of the clitoris. This bone receives the name **os clitoridis**.

**Arteries and Nerves of the Clitoris.**—Each crus receives a branch (arteria profunda clitoridis) from the **internal pudic artery,** while the glans is supplied by branches of the **dorsal arteries** of the clitoris (arteriæ dorsalis clitoridis). The nerve supply of the clitoris is derived partly from the **hypogastric sympathetic plexus** and partly from the **dorsal nerves** of the clitoris.

**Bulbus Vestibuli.**—The bulbus vestibuli is a mass of erectile tissue, in the female, which corresponds developmentally to the corpus spongiosum urethræ of the male. In the female the fusion of the two halves of this structure is not nearly so complete as in the male, for the vagina and urethra separate the bulbus vestibuli into two lateral portions which are only slightly connected in front by a narrow median part called the **pars intermedia.** Each lateral portion of the bulb is thick and massive posteriorly, and more pointed in front where it joins the pars intermedia. It rests against the side wall of the vagina, and upon the superficial aspect of the triangular ligament. Superficially it is covered by the bulbo-cavernosus muscle. The pars intermedia lies above the urethra, and becomes continuous with the tissue of the glans clitoridis. It represents one-half of the corpus spongiosum urethræ of the male.

The bulbus vestibuli is for the most part composed of minute convoluted blood-vessels, held together by a very small amount of connective tissue. These vessels frequently anastomose with one another, and those of each lateral half communicate with the vessels of the pars intermedia and the glans clitoridis.

The blood-supply of the bulb is derived on each side from a branch (arteria bulbi vestibuli) of the internal pudic.

## The Glands of Bartholin.

The **glands of Bartholin** (glandulæ vestibulares majores) are placed one on each side of the lower part of the vagina, and represent Cowper's glands in the male. They are often overlapped by the posterior ends of the bulbus vestibuli, and are covered by the bulbo-cavernosus muscle. Each is about the size and shape of a small bean, and possesses a long slender duct which opens into the urinogenital cleft in the angle between the attached border of the labium minus and the vaginal opening.

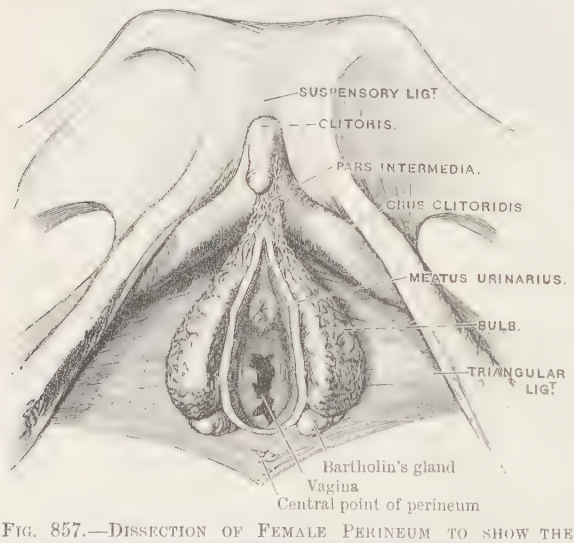

Fig. 857.—Dissection of Female Perineum to show the Clitoris, the Bulb of the Vestibule, and Bartholin's Glands (D. J. Cunningham).

## Development of the Urinogenital Organs.

In tracing the developmental history of the urinogenital system we may for convenience begin with an embryo of fifteen days old. About this time a duct, which runs in a longitudinal direction, and occupies a position on the outer side of the protovertebral somites, begins to develop on each side of the body. With the exception of the anterior portion of the cloaca and the proximal part of the allantois, this duct, which has received the name of **Wolffian duct,** is the earliest formed structure from which, or in connexion with which, the parts of the adult urinogenital system arise.

The Wolffian duct serves as the canal, or duct, for the primitive secretory organ or mesonephros of the embryo. With the atrophy of the mesonephros the duct suffers modification, yet both sexes in the adult possess structures which have their embryonic origin from the Wolffian. In the male the **canal of the epididymis**, the **vas deferens**, and the **common ejaculatory duct**, are to be looked upon as directly developed from the Wolffian duct of the embryo; while in the female the **longitudinal duct of the parovarium** and the **hydatids of Morgagni** are rudimentary structures having a like origin. Further, the **ureter** and its **pelvis**, together probably with the complicated system of

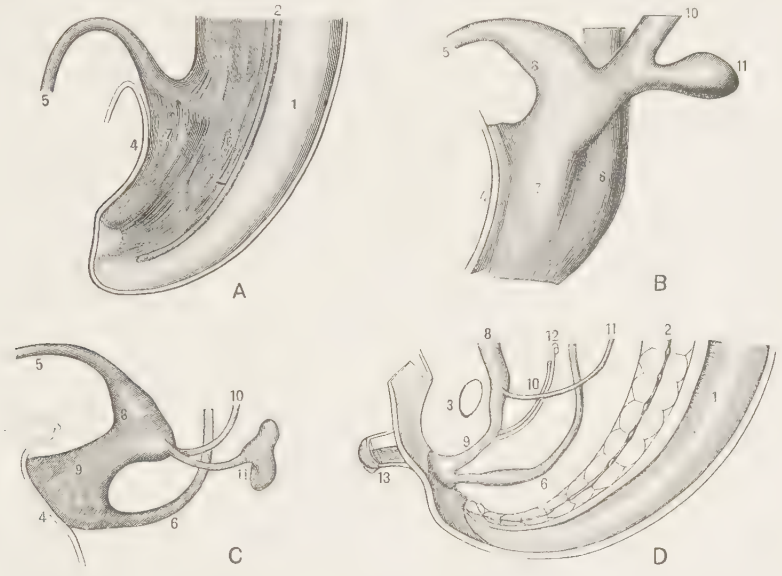

FIG. 858.—DEVELOPMENT OF THE BLADDER, URETER, AND KIDNEY. From the models by Professor Keibel.

A. Caudal portion of an embryo of 15 to 18 days old. The cloaca is relatively very large, and is not yet joined by the Wolffian ducts; an indication is present of the separation of the cloaca into dorsal or rectal, and ventral or urinogenital, subdivisions.

B. The cloaca of an older embryo—25 to 27 days old. The subdivision of the cloaca is more clearly marked. The Wolffian duct is seen joining the anterior subdivision, and from the lower part of the duct an outgrowth is present, which gives origin to the ureter and the kidney.

C. Still older stage (36 to 37 days old). The ureter has acquired a separate opening into the developing bladder which is placed upon the same level as that of the Wolffian duct. The kidney is much more advanced, and the rectum is becoming separated from the urinogenital canal.

D. Female embryo 8½ to 9 weeks old. The openings of the ureter and genital ducts have become separated by a considerable interval. The urinogenital canal and rectum have acquired separate openings.

1, Spinal cord; 2, Notochord; 3, Pubic symphysis; 4, Cloacal membrane, forming the floor of the ectodermal cloacal fossa; 5, Allantoic canal; 6, Rectum, or rectal subdivision of cloaca; 7, Urinogenital subdivision of cloaca; 8, Bladder; 9, Urinogenital canal; 10, Wolffian duct; 11, Ureter (or ureter and developing kidney); 12, Müllerian duct; 13, Genital eminence.

**kidney tubules** which open into it, arise in both sexes as an outgrowth from the Wolffian duct. In the male the **vesicula seminalis** also arises as a diverticulum of the Wolffian duct (Fig. 860).

The primitive secretory organ, the **mesonephros**, or Wolffian body develops in connexion with the anterior part of the Wolffian duct (p. 32), and is, during the early life of the embryo, a most important structure. With the development of the permanent kidney the mesonephros atrophies, yet some of its tubules persist in the adult. The **vasa efferentia**, the **ductuli aberrantes**, and the rudimentary **paradidymis** (organ of Giraldés) in the male, and the rudimentary tubules of the **parovarium** (epoophoron) and of the **paroophoron** in the female, are structures which owe their origin to tubules of the mesonephros.

Soon after the formation of the Wolffian ducts two other longitudinally-disposed canals, called the **Müllerian ducts**, are developed. These open at their cephalic ends into the body cavity, and at their caudal ends, unlike the Wolffian ducts, they unite with one another in the middle line. From them are formed, in the female—the **Fallopian tubes**, the **uterus**, and the **vagina**; and in the male—the **hydatids** of the testis and the **utriculus prostaticus**.

The Wolffian and Müllerian ducts open at their caudal ends into the ventral or

urinogenital part of the **cloaca**, which in the course of development becomes transformed into the **bladder** and the **urinogenital canal** of the embryo (Figs. 858 and 860). The developing ureter at first arises as a diverticulum from the Wolffian duct, at a short distance from the point where the latter joins the cloaca. Soon, however, the ureters acquire independent openings into the cloaca, which become gradually shifted further from one another and from those of the Wolffian ducts. The ureters are now found to open into the anterior portion of the cloaca which lies nearer to the head of the embryo than the part with which the Wolffian ducts are connected. This cephalic portion receiving the ureters becomes, in the male, the bladder and the upper part of the prostatic urethra; in the female, the bladder and the entire urethra (Fig. 861). The caudal part, lying below the level of the entrance of the Wolffian ducts, is the urinogenital canal, and is represented in the adult male by the lower part of the prostatic and by the membranous portions of the urethra; in the female by the part of the urinogenital fissure which immediately surrounds the openings of the urethra and vagina (Fig. 861). The united Müllerian ducts open into the lower part of the cloaca or urinogenital canal, between the Wolffian ducts of opposite sides. In the male the position of this opening, which is represented in the adult by the opening of the uterus masculinus, remains almost unchanged; in the female, on the other hand, the urinogenital canal becomes relatively shorter during development, and thus the opening, which in this sex is represented by the orifice of the vagina, comes to the surface at the bottom of the urinogenital fissure (Fig. 861). The cavity of the developing bladder is directly continuous above with that of the allantois, and by some authorities the bladder is described as arising as a dilatation of the proximal part of the allantois.

When the ectodermal **cloacal fossa** is formed, after the complete separation of the cloaca into anterior or urinogenital, and posterior or rectal parts, it communicates at first with the rectum behind and later on with the urinogenital canal in front (p. 45). The fossa is bounded laterally by well-marked skin folds, the **labio-scrotal folds**, and at its anterior end is situated the **genital eminence**. This eminence becomes the main portion of the **penis** or of the **clitoris**, and its posterior surface is grooved longitudinally in such a manner that the proximal end of the groove lies near the opening of the urinogenital canal into the cloacal fossa.

*In the male* the lips of this groove on the genital eminence, meeting together, form a canal which, in the adult, traverses the penis as the terminal part of the urethra. The lateral margins of the cloacal fossa, behind the genital eminence, meet together, and fusing in the middle line, convert the fossa into a canal, which completes the spongy portion of the adult urethra. In this way all the cloacal fossa lying in front of the rectum, and the groove on the genital eminence, become closed over to form the third part of the urethra. The spongy part of the urethra is thus derived from the *ectodermal cloacal fossa* and the groove on the genital eminence, while the prostatic and membranous parts owe their origin to the *endodermal cloaca*.

*In the female* the margins of the ectodermal cloacal fossa remain separate throughout life, and the fossa persists as the **urinogenital cleft**. The groove on the genital eminence closes over, but does not form a canal as in the male. The urinogenital canal, at first like that of the male, becomes relatively shorter and shorter during development, and, as a result, the lower end of the fused portions of the Müllerian ducts, which opens into the canal, and from which the **vagina** is formed, appears in the adult to open directly into the fossa (urinogenital space) behind the channel leading from the bladder. From the latter channel is formed the female urethra (Fig. 861).

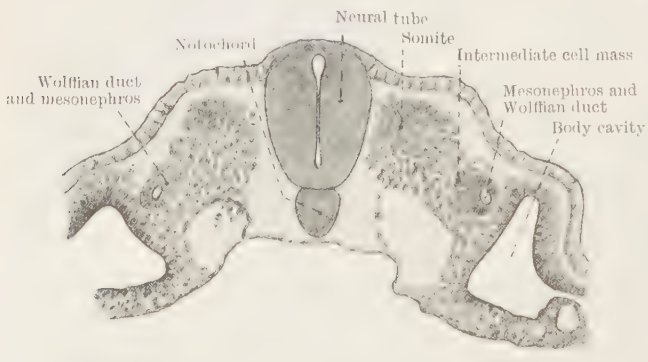

FIG. 859.—TRANSVERSE SECTION THROUGH THE BODY OF A FOWL EMBRYO.

**Wolffian Duct and Embryonic Secretory Organ.**—The **Wolffian duct** arises in the mesoblast, about the fifteenth day, as a solid cord of cells occupying a position immediately to the outer side of the mesoblastic somites and to the inner side of the body cavity. When first recognised the duct lies

immediately beneath the epiblast, and as it grows backwards to reach the cloaca it is often found to be intimately connected with the epiblast. This close connexion of the duct with the epiblast, in the early stages, is by some authorities supposed to indicate a primitive epiblastic origin of the canal, but by others, and apparently with more reason, to be a trace of the opening of ducts on the surface of the body, such as exists in connexion with the excretory organs of lower animals. During the third week the cellular cord which represents the Wolffian duct acquires a lumen, and about the end of the same week the duct in its growth reaches the cloaca. As soon as the cloaca has become divided into dorsal and ventral subdivisions, the Wolffian duct is seen to end in the caudal part of the ventral subdivision, which becomes the urinogenital canal (Fig. 860).

The **Wolffian body** or **mesonephros** is developed in the mesoblast of the "intermediate cell mass," immediately adjoining the Wolffian duct, and consists of a number of transversely-arranged canals or tubules, each of which opens by one end into the Wolffian duct, while its other extremity ends blindly. These transverse tubules, like the canal into which they open, are at first solid cellular structures, and only later acquire a distinct lumen. Increasing rapidly in size and number, the tubules become twisted and tortuous, and the blind end of each dilates to form a capsule invaginated upon itself and containing a bunch of capillary blood-vessels similar to the glomeruli of the adult kidney. It would appear that primitively one tubule is developed in the portion of the intermediate cell mass (nephrotome) corresponding to each mesoblastic somite, but, in higher vertebrates at all events, such a correspondence between the number of somites and the number of tubules cannot be demonstrated. In the posterior part of the Wolffian body the number of tubules is very numerous, and probably far greater than the number of segments in this region. The tubules when formed appear to increase by a kind of budding. The tubules in the anterior part atrophy and disappear at a very early time, even while others are being formed towards the hind end of the embryo. When at its greatest development (fifth to eighth week) the mesonephros forms a relatively large glandular mass, composed of tubules resembling in a general way those of the adult kidney, which projects into the dorsal part of the body cavity, and extends from the region of the liver to the caudal end of the body cavity. Along its outer side lies the Wolffian duct.

In anamniate vertebrates, fishes, and amphibia, the mesonephros persists as the secretory organ of the adult.

FIG. 860.—DIAGRAM TO ILLUSTRATE THE MANNER IN WHICH THE URETER, THE VAS DEFERENS, AND THE BLADDER ARISE IN THE EMBRYO.

The structures developed from the cloaca are indicated in blue, those from the Wolffian duct in red, and the ectoderm in black.

The manner in which the rectum and bladder become separated and acquire openings into the ectodermal cloacal fossa is shown in II. and III. (A. H. Young and A. Robinson).

| CM. | Ectoderm of cloacal fossa. | VD. | Vas deferens. |
| | | VS. | Seminal vesicle. |
| K. | Pelvis of Kidney. | WD. | Wolffian duct. |

**Pronephros.**—From what is known regarding the development of lower animals, it seems certain that the Wolffian duct originally served as the duct of a still earlier secretory organ called the **Pronephros**. The pronephros is formed nearer to the head end of the embryo than the later appearing mesonephros, and its tubules, which in many ways resemble those of the mesonephros, differ from them in that they open directly into the body cavity, and in being derived from the lining mesoblast of the body cavity. It is possible that some of the tubules which in man lie far forwards at the anterior end of the mesonephros, and which do not appear to be functional even during embryonic life, may represent the pronephros of lower vertebrates. Tubules occur in all segments from the sixth cervical to the last lumbar.

As the permanent kidney is developed the mesonephros atrophies; a portion of it, however, is retained *in the male*, and forms the excretory apparatus of the testis. The

Wolffian duct becomes the canal of the epididymis and the vas deferens of the adult (see p. 1204). *In the female*, when the permanent kidney is formed, the mesonephros and its duct undergo atrophy to a greater extent than in the male, and they are only represented in the adult by the rudimentary structures present in the broad ligament of the uterus (see p. 1205).

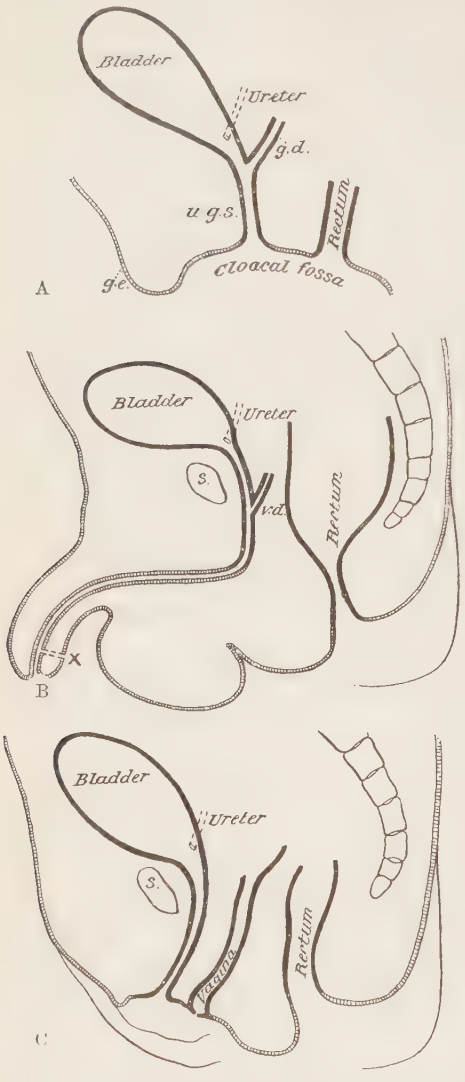

FIG. 861. — DIAGRAMMATIC REPRESENTATION AND COMPARISON OF THE MANNER IN WHICH THE URINOGENITAL PASSAGES ARISE IN THE TWO SEXES.

In each case the hypoblast is indicated by a thick black line, while the epiblast is shown by a double line with cross shading.

A. Represents a stage passed through by both sexes, and illustrates the connexions of the urinogenital ducts and of the rectum with the ectodermal cloacal fossa; *gd*, indicates the position where the Wolffian and Müllerian ducts open into the urinogenital canal; *ge*, genital eminence; *ugs*, urinogenital canal.

B. Male condition. The greater portion of the urethral canal is ectodermal in origin, and is derived from the ectodermal cloacal fossa and the groove on the genital eminence by the meeting of their lateral boundaries. (The portion of the canal which is usually the last to be closed in is indicated at *x*.) The upper part of the urethra is endodermal in origin. The position where the genital ducts (in the male represented by the vasa deferentia and uterus masculinus) join the urinogenital canal is indicated at *vd*; *s*, symphysis pubis.

C. Female condition. Owing to the shortening of the urinogenital canal (*ugs*, in A) and the rapid growth of the vagina the urethral and genital openings come to lie in the bottom of the urinogenital fissure. The deepest part of this fissure, immediately surrounding the openings, is formed by endoderm derived from the urinogenital canal.

**Ureter and Permanent Kidney.**— The kidney and ureter arise as a tubular diverticulum from the Wolffian duct close to the point where the latter joins the cloaca. This diverticulum is seen first during the fourth week, and grows from behind forwards, dorsal to the body cavity. Even in its very early condition the portion of the outgrowth which lies nearest to the Wolffian duct, and from which the adult ureter is developed, is more slender than the distal part, which becomes branched, and grows out to form the pelvis and calyces of the ureter. The uriniferous tubules of the kidney appear to arise as branching tubular outgrowths from the calyces. The blind distal end of each tubule soon dilates to form a capsule which, becoming invaginated on itself, encloses a tuft of capillary blood-vessels. The Malpighian corpuscles arising in this manner are found in the human kidney as early as the eighth week.

According to many embryologists it is only the collecting tubules that are formed in this manner, and the other tubules of the kidney have a mesoblastic origin similar to that of the tubules of the mesonephros and independent of the outgrowth which gives origin to the ureter and its pelvis. These authorities state that the kidney tubules arising in the mesoblast, only later acquire connexions with the outgrowths from the ureter.

It is possible that the tubules which give rise to the permanent kidney really lie in series with those which form the mesonephros, and hence begin where the latter cease to be formed, namely at the first sacral segment.

As the ureter increases in length, it becomes separated from the Wolffian duct, and acquires a distinct opening into the anterior part of the cloaca nearer the head of the embryo than that of the Wolffian duct. This part of the cloaca receiving the ureters becomes the bladder. The kidney is at first a distinctly lobulated body, and shows at birth, and sometimes even in the adult, traces of its original subdivision into lobule.

**Bladder.**—The bladder is formed from

the upper part of the anterior subdivision of the cloaca (Figs. 858 and 860), which increases in width as the openings of the ureters become shifted further from one another. Inferiorly the anterior part of the cloaca remains narrow, and forms the urinogenital canal. At a very early stage the triangular surface, known in the adult as the **trigonum vesicæ**, is to be recognised. From the cephalic end of the developing bladder the allantoic canal extends to the umbilicus; but the allantois loses its lumen in the fifth week, and the portion enclosed within the body of the embryo, known as the **urachus**, becomes converted into the fibrous cord found in the adult connected with the bladder apex.

The cavity of the allantois is sometimes not lost so early, and in rare cases it has been found persisting in the child or adult as a pervious channel extending from the apex of the bladder to the umbilicus. Here it may open on the surface of the body.

By some authorities the bladder is stated to arise as a dilatation of the proximal part of the allantois rather than from the cloaca itself. The distinction, however, does not seem to be important, and probably both the cloaca and the allantois share in its formation.

**Male Urethra.**—The urethra in the male is composed of two parts which are developmentally distinct. One of these corresponds to the **prostatic** and **membranous** portions of the adult, and owes its origin to the *endodermal* cloaca, while the other part corresponds to the **spongy portion** of the adult, and arises in connexion with the *ectodermal* cloacal fossa and genital eminence (Fig. 861). The upper part of the prostatic urethra has an origin similar to that of the bladder, and is derived from the upper portion of the urinogenital subdivision of the cloaca; the lower prostatic and the membranous parts are formed from the urinogenital canal of the embryo. The spongy portion of the adult urethra is developed superficial to the cloacal membrane which separates the ectodermal cloacal fossa from the endodermal cloaca. This ectodermal part of the urethral canal is formed by the meeting of the lateral boundaries of the anterior part of the cloacal fossa, where they lie in front of the anal opening, and also by the closing of the lips of a groove which appears on the genital eminence. In the early stages the position of the greater part of the future urethra is indicated by a solid cord-like mass of epithelial cells, which forms the so-called "urethral septum." This becomes broken down later on to form the groove or gutter which is converted into the urethral canal (see p. 1206). The median raphe, extending from the anus forwards along the urethral surface of the penis in the adult, indicates the line of fusion along which the spongy part of the urethra has been closed in and converted into a canal. The last portion of the groove to be closed over is the extreme anterior part which lies behind the base of the glans penis. In some rare cases failure of the margins of the groove to unite in this situation causes the urethra to appear to terminate at this point. In other cases a greater arrest of development leaves the cloacal fossa open, and we have a condition retained which resembles to a certain extent the normal arrangement of the parts in the female. To such abnormalities of the urethra the term **hypospadias** is applied.

**Female Urethra.**—In the female the urethra is developed from the part of the anterior portion of the cloaca which lies below the developing bladder, and above the openings of the Müllerian and Wolffian ducts. The part below these openings, the urinogenital canal, during the course of development becomes relatively shorter and shorter, and finally forms the epithelium at the bottom of the urinogenital cleft immediately surrounding the urethral and vaginal openings of the adult. Thus in the adult the urethra, which originally led into the urinogenital canal, opens into the urinogenital fissure.

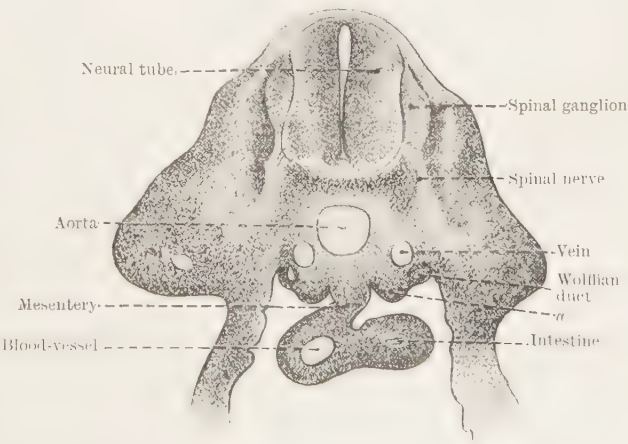

Fig. 862.—Transverse Section through the Body of a Rat Embryo.
The position where the germinal epithelium arises is indicated at *a*.

In some mammals, such as the hedgehog, the shortening of the urinogenital canal does not take place in the female during development, and in these animals a single aperture exists for the urinary and genital systems. The

hymen is placed where the fused Müllerian ducts (vagina) open into the urinogenital canal.

**Sexual Glands.**—In the development of the sexual glands, male and female, a differentiated thickened portion of the peritoneal epithelium is first recognised. This specialised epithelium, which has received the name of **germinal epithelium**, is situated to the inner side of the mesonephros and of the Wolffian and Müllerian ducts. Here it covers a longitudinally-disposed ridge or elevation called the **genital ridge**. The germinal epithelium is not strictly limited to this ridge, but extends to some extent beyond its limits. The genital ridge is soon found to have numerous epithelial cells embedded in its connective-tissue stroma which appear to originate, in both sexes, by a proliferation from the deep surface of the germinal epithelium covering the ridge. From these epithelial cells the seminiferous tubules of the male, and Graafian follicles with their contained ova of the female are developed.

*In the male*, as early as the thirty-third day, the epithelial cells embedded in the stroma of the developing testis have become arranged into a network of anastomosing cords within which certain larger cells are seen to be irregularly scattered. These larger cells have received the name of **primitive sperm cells**, and are relatively few in number. They undergo frequent division, and in the later stages are not to be distinguished from the other cells of the cords. The cellular cords undergo direct transformation into the **seminiferous tubules** of the testis, but the excretory apparatus, including the **rete testis** and **tubuli recti**, is derived by outgrowths from the anterior tubules of the mesonephros. At a very early stage the superficial part of the stroma of the developing testis, becomes denser, and gives origin to the **tunica albuginea**.

It has been stated that the sexual epithelium of the testis, unlike that of the ovary, is not derived from the germinal epithelium, but that it has its origin in an outgrowth of the mesonephros. The course of the development of the sexual glands is without doubt extremely difficult to follow.

*In the female* large epithelial cells are found in the stroma of the developing ovary, beneath the germinal epithelium, as early as the thirty-third day. These **primitive ova** are much more numerous than the primitive sperm cells of the male, and form a very characteristic feature of the developing ovary. At first they lie isolated, but later—about the fifth week—they become surrounded by other smaller cells having a like origin from the germinal epithelium. Each primitive ovum surrounded by its cells becomes a **primitive follicle**, the further development of which has already been described (p. 1184). The proliferation of cells from the germinal epithelium goes on until the seventh month, and during the later stages the epithelium has the appearance of growing down into the stroma in the form of long branching cellular processes which break up into little nests of cells to form the future follicles (p. 851). It is extremely doubtful if any new ova arise after birth.

**Generative Ducts.**—As has been already stated, the male ducts arise from the Wolffian, and the female from the Müllerian ducts of the embryo. Both sexes at first possess well-developed Wolffian and Müllerian ducts, which are arranged in a very definite manner. The Wolffian ducts communicating directly with the tubules of the mesonephros lie at first parallel to, and at a considerable distance from one another. As they pass backwards towards the caudal end of the embryo they approach one another, and each becomes enclosed in a fold of peritoneum called the **plica urogenitalis**. More caudally the ducts become closely approximated to each other, are embedded in a cord-like mass of connective tissue, to which the term **genital cord** is applied. They finally open into the lower part of the anterior subdivision of the cloaca.

The Müllerian ducts, opening freely into the body cavity at their cephalic ends, lie to the outer side of the Wolffian ducts. As they are traced caudally they cross the Wolffian ducts and enter the genital cord, within which they unite and form a canal, which occupies the mesial plane, and opens into the lower part of the anterior subdivision of the cloaca, between the Wolffian ducts. The manner in which the ureters become separated from the Wolffian ducts has already been described.

**Ducts in the Male.**—The seminiferous tubules of the testis become connected with the Wolffian duct through a fusion with the anterior canals of the mesonephros. At the place where this fusion occurs the **rete testis** and the **tubuli recti** are formed. The connexion is definitely established in the third month. The number of tubules taking part varies considerably, but corresponds to the number of **vasa efferentia** found in the adult. The connecting tubules becoming much convoluted, just as they join the Wolffian duct, form the **coni vasculosi**. The **canal of the epididymis** is directly formed from the anterior part of the Wolffian duct, and the **vas deferens** from the more

posterior portion. The **ductuli aberrantes** and the rudimentary tubules of the **organ of Giraldes** are to be looked upon as persistent tubules, of a more posterior portion of the Wolffian body, which have failed to become connected with the tubules of the testis. The **seminal vesicles** are developed in the third month as evaginations which arise from

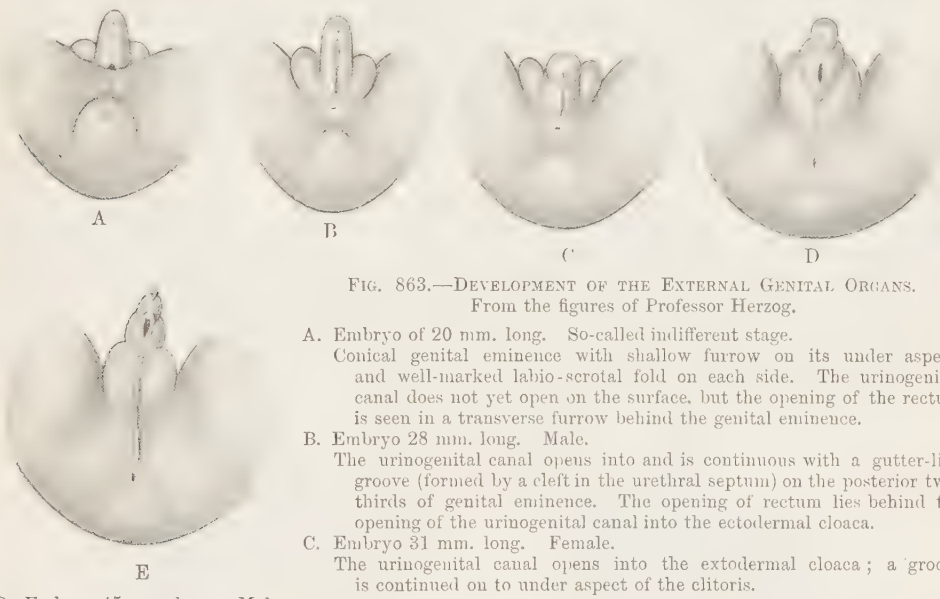

FIG. 863.—DEVELOPMENT OF THE EXTERNAL GENITAL ORGANS. From the figures of Professor Herzog.

A. Embryo of 20 mm. long. So-called indifferent stage.
Conical genital eminence with shallow furrow on its under aspect, and well-marked labio-scrotal fold on each side. The urinogenital canal does not yet open on the surface, but the opening of the rectum is seen in a transverse furrow behind the genital eminence.

B. Embryo 28 mm. long. Male.
The urinogenital canal opens into and is continuous with a gutter-like groove (formed by a cleft in the urethral septum) on the posterior two-thirds of genital eminence. The opening of rectum lies behind the opening of the urinogenital canal into the ectodermal cloaca.

C. Embryo 31 mm. long. Female.
The urinogenital canal opens into the extodermal cloaca; a groove is continued on to under aspect of the clitoris.

D. Embryo 45 mm. long. Male.
Formation of scrotum. The labio-scrotal folds, formerly best marked at sides of genital eminence, have grown backwards and united behind to form the raphe scroti. The scrotum embraces the base of the genital eminence or penis. The glans is very prominent, and the cleft to form the urethra does not yet reach as far as the base of the glans.

E. Embryo 60 mm. long. Male.
Behind the glans penis the urethra opens in a diamond-shaped fossa in the posterior wall of which the median raphe ends. The prepuce is formed behind the constriction which marks off the glands, and as it grows forwards the constriction disappears.

In each case a little horn-like process of epithelium is present on the summit of the genital eminence.

the Wolffian ducts, near their caudal extremities. Each at first has the appearance of a longitudinal groove in the wall of the vas deferens, which closes over and becomes cut off from the main tube except at the point where later on the duct of the seminal vesicle joins the vas deferens. From the part of the cloaca into which the Wolffian ducts open the prostatic urethra of the adult is derived. The Müllerian ducts atrophy in the male embryo, but the **hydatids** of the testis are rudimentary remains of their anterior portions, while the **sinus pocularis** represents the lower fused portions which, in the embryo, occupy the genital cord.

**Ducts in the Female.**—The Müllerian ducts in the female retain their openings into the body cavity, and their anterior portions become the Fallopian tubes. Their fused posterior parts, which at first join the urinogenital canal, give rise to the **uterus** and **vagina**. The manner in which the original position of the opening of the Müllerian ducts becomes shifted, by the shortening of the urinogenital canal, so as to appear at the bottom of the urinogenital fissure, has already been described.

The vaginal portion of the fused Müllerian ducts is at first relatively very short, and at the point where it opens into the urinogenital canal a slight fold appears, which is the future **hymen**. The vagina increases rapidly in length as its opening moves downwards towards the urinogenital cleft. In the human embryo during the third month the closely-applied Müllerian ducts, which higher up have fused to form the uterus, are represented at their lower ends by a pair of rapidly-elongating solid cellular cords, which at a later stage break down to form the vagina.

The Wolffian ducts and the mesonephros atrophy in the female, but traces of them are to be found in the parovarium and paroophoron of the adult. In the fœtus the Wolffian duct can be traced along each side of the uterus as far as the upper end of the vagina.

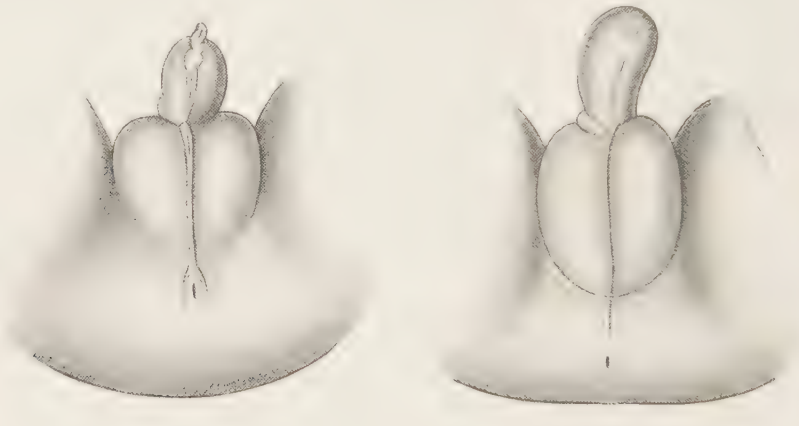
**Prostate.**—The glandular portion of the prostate arises as a series of solid outgrowths from the epithelium of the urinogenital canal during the third month. The outgrowths,

which are at first simple, become branched and finally acquire a lumen. They are arranged in three groups—an upper and a lower dorsal, and a ventral group. The glands of the ventral group soon become reduced in number and often completely disappear; those of the upper dorsal group form the chief part of the gland.

**Cowper's glands** arise in the third month, and appear to be developed from the epithelium of the urinogenital canal. Since in the Echidna these glands have been shown to have an ectodermal origin, and as in man their ducts are connected with a part of the urethra which is ectodermal in its origin, it is possible that further investigation will show that Cowper's glands arise superficial to the cloacal membrane and form the ectoderm in the human embryo.

The **glands of Bartholin** arise as epithelial outgrowths in the same manner as Cowper's glands.

**External Genital Organs.**—The external genital organs are developed in the region of the ectodermal cloacal fossa, and those of the male and female cannot be distinguished from one another in the earlier stages. The ectodermal cloacal fossa, at first very narrow, is completely filled by a wedge-shaped mass of ectodermal cells. At its anterior end lies the **genital eminence**, a somewhat conical projection which represents the future penis or clitoris. The genital eminence appears very early, even before the endodermal cloaca has become divided into urinogenital and rectal subdivision. On each



A B

Fig. 864.—External Genital Organs in Male Fœtus. From figures of Professor Herzog.

The prepuce has grown forwards so as to cover glans completely. The urethra has been continued forwards to the apex of the glans. As in the body of the penis the portion of the urethra, which traverses the glans, is at first represented by a cleft in the "urethral septum."

side of it is a prominent fold-like projection—**labio-scrotal fold**—which is continued backwards to bound the ectodermal cloacal fossa laterally (see Fig. 863). An opening of the rectum on the surface of the body is established at an earlier date than that at which the communication between the urinogenital canal and the ectodermal fossa is formed. As the later opening becomes established, the wedge-shaped mass of ectoderm, which fills all the anterior part of the fossa, and is continued as a kind of septum into the substance of the genital eminence, becomes converted into a groove or gutter. At a later time the margins of this groove, meeting in the middle line, give rise to a canal which is the representative of the spongy portion of the urethra. The mass of ectoderm which becomes cleft to form the groove, and later on forms the lining of the spongy portion of the urethra, has been termed the **urethral septum**. The septum is cleft from behind forwards, and the groove which results is closed in gradually from behind forwards to form the urethra. The part of the septum which extends forwards into the glans penis remains solid, after the rest of the canal has been formed, hence the urethra for some time appears to end in a little diamond-shaped fossa situated at the base of the glans which at the time forms a prominent knob-like projection on the apex of the genital eminence (Fig. 863, E). At a later time the septum within the glans is cleft and converted into a canal, and the urethra is then continued to the end of the penis. The glans is at first uncovered and marked off from the rest of the penis by a circular constriction behind which the prepuce takes origin. As the prepuce grows forwards the groove disappears and the glans becomes covered. While the

spongy portion of the urethra is being formed, the labio-scrotal folds grow backwards and meet together in the middle line behind the penis and in front of the anus. From them is formed the scrotum of the adult, and the line along which they meet is the raphe scroti.

In the female the labio-scrotal folds do not fuse together, but become the labia majora, and the interval between them the urinogenital cleft of the adult. A groove arises on the genital eminence, but it closes in again without forming a canal, and hence when the urinogenital canal, which forms the urethra, opens into the ectodermal fossa it is not continued into the clitoris.

## THE MAMMARY GLANDS.

The **mammary glands** (mammæ) or breasts are accessory organs connected with the female reproductive system. Each gland is situated in the superficial fascia covering the anterior aspect of the thorax, and usually extends from the level of the second or third to that of the sixth rib. The hemispherical projection formed by the gland lies upon the superficial aspect of the pectoralis major and to a less extent upon the serratus magnus muscle. Near the summit of each mammary elevation, and usually at the level of the fourth or fifth rib, is placed the wart-like **nipple** (papilla mammæ), which is pierced by the minute openings of the lactiferous ducts and is surrounded by a coloured circular area of skin called the **areola**. The skin covering the nipple is thrown into numerous wrinkles, and on the areola exhibits many minute rounded projections due to the presence of underlying cutaneous glands. These have received the name of **Montgomery's glands** or **glandulæ areolares**, and are considered to represent rudimentary portions of the mammary gland. The colour of the nipple and areola varies with the complexion of the individual, but in young subjects they are usually of a somewhat rosy-pink colour, which changes to a deep brown during the second and third months of first pregnancy. Also during pregnancy the areola increases in size and its glands become more marked. The nipple contains a considerable number of unstriped muscle fibres, and becomes firmer and more prominent as a result of mechanical stimulation.

The size and appearance of the mammary glands vary much, not only in the different races of mankind, but also in the same individual under different conditions. In the young child the mammæ are small, and there is little difference between those of the male and female. Their growth is slow until the approach of puberty, and then the female mammæ increase rapidly in size. At each pregnancy the mammæ become large, and they attain their greatest development during lactation. The size of the mamma depends partly on the amount of superficial fat and partly on the amount of glandular tissue present.

FIG. 865.—DISSECTION OF THE MAMMARY GLAND.

**Structure of the Mamma.**—The mamma is composed of a mass of glandular tissue traversed and supported by strands of fibrous connective tissue, and covered by a thick layer of fat. The glandular tissue, to which the term **corpus mammæ** is applied, forms a somewhat conical mass whose apex corresponds to the position of the nipple while its base is loosely connected to the fascia covering the pectoralis major and serratus magnus muscles. In section the corpus mammæ is readily distinguished from the surrounding fat by its firmer consistency and by its pinkish-white colour. The corpus mammæ is composed of lobes and lobules, and its superficial aspect and edges

are very uneven, the inequalities of its surface being filled up by processes of the fatty tissue which forms a covering for the gland. This fatty covering is incomplete beneath the areola, and here the lactiferous ducts pass into the nipple. The gland is composed of fifteen to twenty **lobes** (lobi mammæ) which radiate from the nipple, each lobe being quite distinct from the others and possessing its own duct. The lobes are subdivided into secondary lobes and lobules, bound together and supported by a considerable amount of connective tissue which forms the **stroma** of the gland.

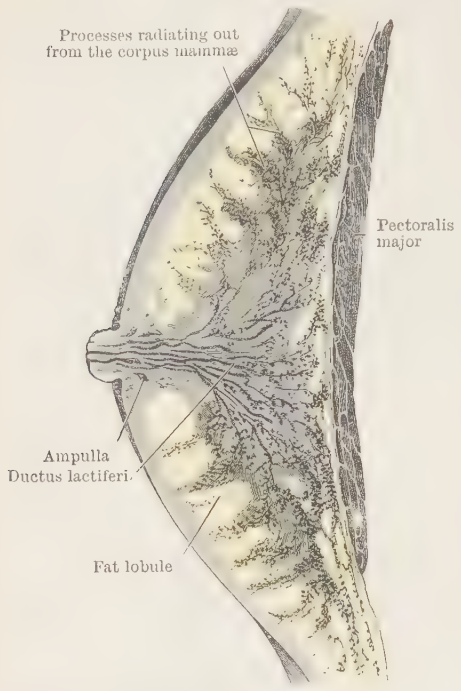


FIG. 866.—SECTION THROUGH A MAMMARY GLAND. Prepared after immersion in nitric acid as recommended by Mr. Harold Stiles. (D. J. Cunningham.)

The alveoli of the gland and the secretory epithelium lining them vary much under different conditions. At puberty the corpus mammæ is chiefly composed of connective tissue stroma and the ducts of the gland. At this time the alveoli are small and few in number. During lactation, when the gland is fully functional, the alveoli are enlarged, distended with fluid, and much more numerous. The epithelial cells are cubical and filled with fat globules. When the gland is not secreting, the alveoli become small and reduced in number, while the cells of the lining epithelium, which are now small and glandular, do not contain fat globules.

The duct (ductus lactiferi) of each lobe, passing towards the nipple, becomes enlarged to form a small spindle-shaped dilatation, called an **ampulla**, or **sinus lactiferi**; then becoming once more constricted, each duct passes, without communicating with its neighbours, to the summit of the nipple, where it opens.

In the male subject the various parts of the mamma are represented in a rudimentary condition.

The presence of milk-glands is characteristic of the class mammalia, and the number of pairs of glands in each group of animals bears some relation to the number of young usually produced at each birth.

**Variations.**—Asymmetry in the development of the mammæ is very common—the left mamma being very often larger than the right. Absence of one or both mammæ is a very rare abnormality, which may or may not be associated with absence of the nipples. When one nipple only is present it is usually the left. The presence of supernumerary glands or nipples is not very uncommon, and a large number of examples are recorded. The term **polymasty** has been applied to cases in which more than the normal number of mammæ are present, and **polythely** to those in which additional glands, in a rudimentary condition, are represented by accessory nipples. Usually the accessory glands, or nipples, are present on the ventral aspect of the thorax, and in most instances they occur below and a little to the inner side of the normal site. When the abnormal glands are found above the normal site they generally lie further from the middle line. Much more rarely accessory glands have been found on the abdomen, in the axilla, or in some other situation, including even the dorsal aspect of the trunk. As many as three extra pairs of mammæ have been found in the same individual, and cases in which the probable representatives of mammary glands were even more numerous have been recorded. Asymmetry is very common in these abnormal structures. It is interesting to note that examples of polymasty and polythely occur in the male rather more frequently than in the female. In some women the accessory breasts have yielded milk during lactation; in other cases the abnormal organs have been very rudimentary, and represented only by a minute nipple or pigmented areola. These cases of polymasty and polythely are supposed to represent a reversion to an ancestral condition, in which more than two mammary glands were normally present, and in which probably many young were produced at each birth. In this connexion it is interesting to observe that usually the accessory glands occur in positions normally occupied by mammæ in lower animals. In the course of the development of the mammary glands in man, specialised areas of the epidermis, similar to those which give origin to the mammary glands, have been observed both above and below the region

in which the adult mammary glands are developed. These areas appear to be present normally, but in most cases they disappear at an early stage in the history of the embryo. In some other mammals rudimentary mammary glands may occur, as, for instance, in lemurs and in some cows.

A slight functional activity of the mammary glands of the male at birth and about the time of puberty is stated to be not a very uncommon occurrence.

**Vessels and Nerves of the Mamma.**—The breast receives its arterial supply from the perforating branches of the **internal mammary artery** and from the **external mammary branch** of the long thoracic. Additional supply is sometimes derived from some of the intercostal vessels. The veins coming from the gland pour their blood into the **axillary** and **internal mammary veins.** Some small superficial veins from the breast join tributaries of the external jugular. The **lymphatics** of the breast are very numerous, and form extensive lymph spaces round the alveoli of the gland. The lymphatic vessels coming from the mamma for the most part join the lymphatic glands of the axilla, but some vessels from the inner part of the breast, following the course pursued by the perforating arteries, join the lymphatic glands situated along the course of the internal mammary artery. The nerve supply of the gland is derived from the **intercostal nerves** of the fourth, fifth, and sixth intercostal spaces. Along the course of these nerves sympathetic filaments reach the breast from the dorsal part of the sympathetic cord.

## DEVELOPMENT OF THE MAMMÆ.

The mammary glands are developed as downgrowths of the ectoderm into the underlying mesoblastic tissue. In the human embryo a thickened raised area of the ectoderm is to be recognised in the region of the future mammary gland at the end of the fourth week. This thickened ectoderm becomes depressed in the underlying mesoblast, and thus the mammary area soon becomes flat, and finally sunk below the level of the surrounding epidermis. The mesoblast, where it is in contact with this downgrowth of the ectoderm, is compressed, and its elements become arranged in concentric layers, which, at a later stage, give rise to the connective tissue stroma of the gland. The depressed mass of ectoderm cells soon becomes somewhat flask-shaped, and grows out into the surrounding mesoblast as a number of solid processes, which represent the future ducts of the gland. These processes, by dividing and branching, give rise to the future lobes and lobules, and much later to the alveoli. The mammary area becomes gradually raised again in its central part to form the nipple. A lumen is only formed in the different parts of this branching system of cellular processes at birth, and with its establishment is associated the secretion of a fluid resembling milk, which often takes place at this time. The ampullæ appear as thickenings on the developing ducts before birth.

In those animals which possess a number of mammary glands—such as the cat, pig, etc.—the thickening of the ectoderm, which is the first indication of the development of these structures, takes the form of a pair of ridges extending from the level of the forelimb towards the inguinal region. These converge posteriorly, and at their terminations lie not far from the middle line. By the absorption of the intermediate portions the ridges become divided up into a number of isolated areas, in connexion with which the future glands arise. Such linear thickenings of the ectoderm have not yet been shown to occur in the human embryo, but the usual positions assumed by the accessory glands when present, leads one to suspect that in all probability the ancestors of man possessed numerous mammary glands arranged, as in lower animals, in lines converging towards the inguinal region.

# THE DUCTLESS GLANDS.

By D. J. Cunningham.

Under this title we include a heterogeneous group of organs, the common feature of which is that the products of their activity are not conveyed from them by means of ducts, but are discharged directly into the vascular system through the veins or lymphatic vessels which take origin within them. This physiological process is termed *internal secretion*, and in the case of certain of these organs the secretion has been shown to exert a profound influence upon the nutritive changes of the body.

The ductless glands include the lymphatic glands, which have been already described with the vascular system; the pineal and pituitary bodies, which have been referred to in the account which has been given of the brain; and the spleen, the suprarenal capsules, the thyroid body, the parathyroids, the thymus body, the coccygeal body, the carotid body—all of which still remain to be studied.

## THE SPLEEN.

The **spleen** (lien) is the largest of the ductless glands. It varies greatly in size in different individuals, and also in the same individual under different conditions, consequently it is difficult to give its average dimensions. Roughly speaking, it may be said to be as a rule about five inches in length and three inches in width at its widest part. It is a soft yielding organ, very vascular, and somewhat purple in colour. It lies far back in the abdominal cavity between the stomach and the diaphragm, and its position is such that, whilst the greater part of the organ is situated in the left hypochondrium, its upper end extends inwards beyond the left Poupart plane, and thus comes to lie in the epigastric region. It is placed very obliquely, and its long axis corresponds closely in its direction to that of the back part of the tenth rib.

**Form and Relations of the Spleen.**—The spleen has the shape of an irregular tetrahedron. The **upper end** (extremitas superior) points inwards and backwards, and is curved to some extent forwards on itself. Of the four surfaces the most extensive is the **diaphragmatic** (facies diaphragmatica), which looks backwards and outwards. It rests upon the back part of the diaphragm, to the curvature of which it is accurately adapted. By the diaphragm it is separated from the ninth, tenth, and eleventh ribs. It is necessary also to remember that the pleura descends between this portion of the chest wall and the diaphragm, and thus comes to lie superficially to the greater part of this diaphragmatic surface of the spleen. The thin basal margin of the lung, which occupies the upper part of the pleural recess, likewise intervenes between the upper part of the spleen and the surface of the body.

In the fœtus and infant, in which the liver is relatively very large, the left lobe of that organ extends to the left so far that it comes as a rule to intervene between a portion of the spleen and the diaphragm. Such a relation is sometimes seen in the adult, but, except in childhood, it is usual for the liver to fall short of the spleen.

The remaining three surfaces of the spleen are turned towards the cavity of the abdomen, and are closely applied to the viscera which support the organ in its place. These three surfaces, which may be grouped together under the one term of *visceral aspect* of the organ, are separated from each other by three ridges which radiate from a blunt and often inconspicuous prominence which may be termed the **intermediate angle** and represents the apex of the tetrahedron. One of these ridges, a salient and prominent border (margo intermedius), extends to the upper end of the spleen, and separates an extensive anterior gastric area from a narrower posterior renal area. A second short border passes backwards to the **posterior angle**, and intervenes between the renal and colic surfaces; whilst the third ridge, often obscurely marked, proceeds forwards to the **anterior angle** and separates the gastric

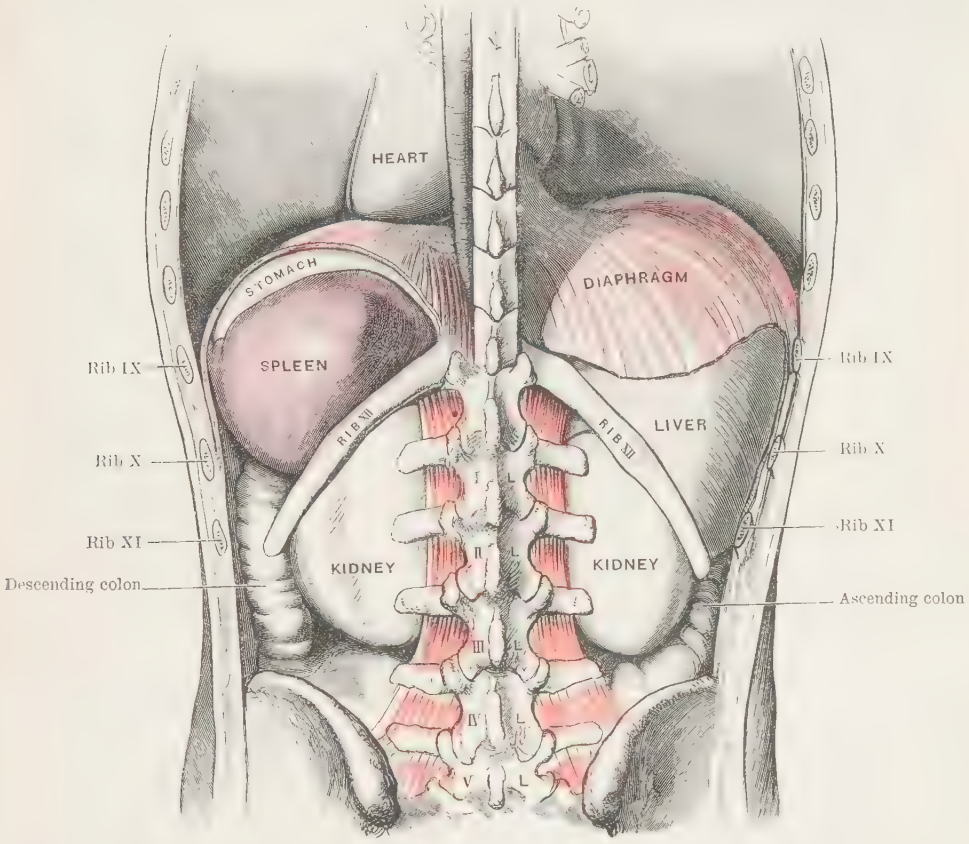

FIG. 867.—DISSECTION OF THE SPLEEN, LIVER, AND KIDNEYS FROM BEHIND, IN A SUBJECT HARDENED BY FORMALIN-INJECTION.

and the colic surfaces from each other. The term colic surface is applied to a triangular area which is mapped out by the two last-named ridges together with the lower border of the organ.

The **gastric surface** (facies gastrica) is the most extensive of the three visceral districts. It is deeply concave, and is moulded on the fundus of the stomach. Within its area, and about an inch or so in front of the margo intermedius, is the **hilum** of the organ. This is a slit, frequently broken up into two or more pieces, which gives passage to the vessels and nerves which enter and leave the spleen. Behind the hilum, and immediately in front of the intermediate angle, there is a depression of variable extent and depth into which the tail of the pancreas is received.

The **renal surface** (facies renalis) is flat and even. It is applied to the anterior surface of the upper part of the kidney, close to its outer border. Sometimes the part of this surface which adjoins the upper end of the organ is applied to the left suprarenal capsule, but as a rule it falls short of that structure.

The **colic surface** (facies basalis) is the smallest of the three visceral areas. It is triangular in form, and looks downwards and inwards, and is in contact with the splenic flexure of the colon and the costo-colic ligament (*vide* p. 1083).

The **anterior border** (margo anterior) of the spleen is sharp and prominent, and intervenes between the gastric and diaphragmatic surfaces. Its leading characteristic is that it is irregularly notched. The **posterior border** (margo posterior) separates the renal from the diaphragmatic surface. It is important to know that, if in the living subject the finger is drawn along the last intercostal space, it will indicate with tolerable accuracy on the surface of the body the position and direction of the posterior border. The **inferior border** (margo inferior) of the spleen intervenes between the diaphragmatic surface and the colic surface. The other margins of the spleen are those which separate the visceral areas from each other, and they have been already noticed.

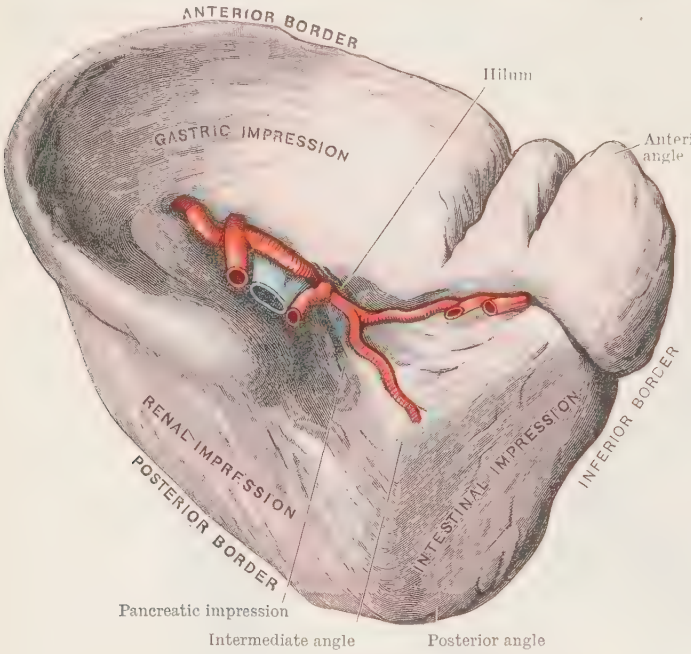

FIG. 868.—THE SPLEEN—VISCERAL ASPECT.

A marked feature of the typically-formed spleen is the great prominence of the **anterior angle**. It forms the most anteriorly-placed part of the organ.

The form of the spleen varies much in accordance with the changing conditions of the neighbouring hollow viscera. Shepherd has shown that there are two extreme forms, viz. the **tetrahedral**, which is described above, and the **orange-segment type**. In the case of the former the colon is distended, and the stomach as a rule more or less empty: the colon displaces the stomach from contact with the lower part of the visceral surface of the spleen, and by its pressure produces the colic impression.

When the spleen presents a form similar to that of the segment of an orange its lower end becomes pointed, and the entire visceral surface is occupied by the renal, gastric, and pancreatic impressions or areas. The colon is as a rule empty and exerts no pressure on the spleen, whilst the stomach is in all probability distended. As Shepherd has shown, every intermediate form of spleen between the two extreme types are met with, and may occur with varying conditions of the hollow viscera, at different times, in the same individual.

**Notches and Fissures.**—The usual number of notches on the anterior border of the spleen is two, although in exceptional cases there may be as many as six or even seven. It is not uncommon to find one or more fissures on the posterior border and also on the parietal surface of the organ (Parsons).

**Peritoneal Relations of the Spleen.**—The spleen is almost completely enveloped by peritoneum, and two folds of peritoneum, viz. the gastro-splenic omentum and the lieno-renal ligament, pass from it. Both of these folds are attached in the neighbourhood of the hilum. The **lieno-renal ligament** proceeds backwards to the anterior surface of the left kidney (p. 1099); the **gastro-splenic omentum** connects the spleen with the fundus of the stomach (p. 1104).

**Accessory Spleens.**—Small globular masses of splenic tissue are not infrequently found in the neighbourhood of the spleen. These are termed **accessory spleens.**

**Blood-vessels, Lymphatics, and Nerves of the Spleen.**—The large **splenic artery** gains the spleen by passing between the two layers of the lieno-renal ligament. It breaks up into several

branches which enter the organ through the hilum. Some twigs proceed from the splenic artery to the stomach, which they gain by insinuating themselves between the two layers of the gastro-splenic omentum. The **splenic vein** is formed in the lieno-renal ligament by the union of the branches which emerge from the hilum of the organ. It joins the superior mesenteric vein to form the vena portæ.

The **splenic plexus of nerves** is an offset from the cœliac part of the solar plexus, and accompanies the arteries into the spleen.

The **lymphatic vessels** leave the spleen at the hilum, and accompany the great vessels. There are no lymphatic channels within the spleen, although they are present in its capsule (Mall).

**Structure of the Spleen.**—In our study of the structure of the spleen we have to consider—(1) the tunica propria, (2) the trabecular framework, (3) the spleen pulp, and (4) the distribution of the blood-vessels and the Malpighian corpuscles.

**Tunica propria** (tunica albuginea).—Subjacent to the serous coating furnished by the peritoneum the spleen is provided with a strong capsule termed the tunica propria. This is formed of fibrous tissue, with a large proportion of elastic fibres and a certain amount of involuntary muscular tissue. It is therefore highly distensible, and perhaps feebly contractile. To the outer surface of this capsule the peritoneum is inseparably attached.

**Trabecular Framework** (trabeculæ lienis).—From the deep surface of the tunica propria numerous processes or trabeculæ are given off, and these penetrate into the substance of the spleen. Some are cord-like, others are in the form of flattened bands, and all are composed of fibrous tissue and involuntary muscular fibres. Within the spleen the trabeculæ branch and re-branch, and join with each other to form a supporting framework for the organ. The blood-vessels, as they enter at the hilum, carry in with them connective tissue sheaths, and these also take part in the formation of the trabecular framework

**Spleen Pulp** (pulpa lienis).—The interstices between the strands of the trabecular framework are filled with spleen pulp. This is supported by a delicate reticulum formed by branching cells. The spaces of the network freely communicate, and are occupied by blood in which there are large numbers of leucocytes, and also large cells special to the spleen. These are termed **splenic cells**, and contain pigment, and not infrequently red blood corpuscles, in their interior.

**Blood-vessels and Malpighian Corpuscles.**—The splenic arteries, as they traverse the spleen, run in the trabeculæ. The small branches ultimately leave these and enter the spleen pulp. As they do so they become ensheathed in a coating of adenoid tissue. At certain points in the course of the arteries this sheath suddenly increases in thickness, and forms small round or oval masses of adenoid tissue upon the vessel. In sections through the spleen these small nodular masses are visible to the naked eye as minute white spots. They are called **Malpighian corpuscles** (noduli lymphatici lienales). The artery rarely passes through the centre of such a corpuscle. As a rule the adenoid tissue is massed chiefly upon one side of the vessel, and a plentiful supply of blood is given to the nodule by means of a capillary network in connexion with the artery on which the Malpighian corpuscle is developed.

The manner in which the minute terminal arteries end in the spleen pulp is peculiar. The wall becomes reduced to the endothelial lining, and the cells forming this gradually separate from each other and become continuous with those of the reticulum of the spleen pulp. The blood therefore flows directly into the meshes of the reticulum of the pulp. The minute radicles of the veins begin in the same way as the arteries end. The walls are gradually built up by the union of cells continuous with the open reticulum, and the blood flowing into the vessels so formed is led away towards the larger veins which occupy the trabeculæ.

**Development of the Spleen.**—It is not until the second month of intrauterine development that the spleen begins to develop. It is formed from mesoderm, and appears in the dorsal mesogastrium in the neighbourhood of the pancreas. After a short time it becomes invaded by blood-vessels, but the Malpighian corpuscles are somewhat late in making their appearance. The spleen grows to the left in the direction of least resistance, protruding the left layer of the mesogastrium before it, and its form is determined by the pressure to which it is subjected by the neighbouring viscera and the abdominal wall.

## THE SUPRARENAL CAPSULES.

The suprarenal capsules (glandulæ suprarenales) are two small flattened organs which lie in the epigastric region, one on either side of the spine, and in intimate relation to the upper end of the corresponding kidney.

The **right suprarenal capsule** is, as a rule, triangular in form, and rests by its base upon the anterior and inner aspect of the upper end of the right kidney. It

is placed between the posterior surface of the right lobe of the liver and that portion of the diaphragm which covers the side of the spine.

The *anterior surface*, which looks outwards as well as forwards, presents two impressions—(1) The one is a narrow flattened strip adjoining the anterior border of the capsule which is overlapped by the inferior vena cava; (2) the second impression comprises the remainder of the anterior surface, and is in contact with

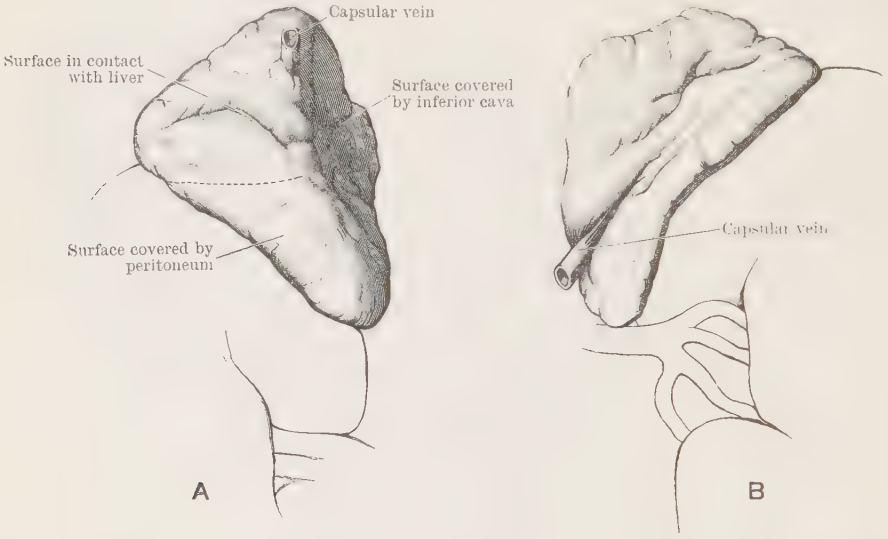

FIG. 869.

A. Anterior surface of right suprarenal capsule. B. Anterior surface of left suprarenal capsule. The upper and inner parts of each kidney are indicated in outline. On the right capsule the dotted line indicates the upper limit of the peritoneal covering.

the liver. Only a small and variable part of the lower portion of the anterior surface of the right suprarenal capsule is covered by peritoneum. On the upper part of the impression for the vena cava, not far from the apex of the capsule, a short fissure termed the **hilum** may be observed. From this issues a short wide vein which immediately enters the vena cava inferior. The *posterior surface* of the right suprarenal capsule is divided by a salient curved ridge into an upper flat

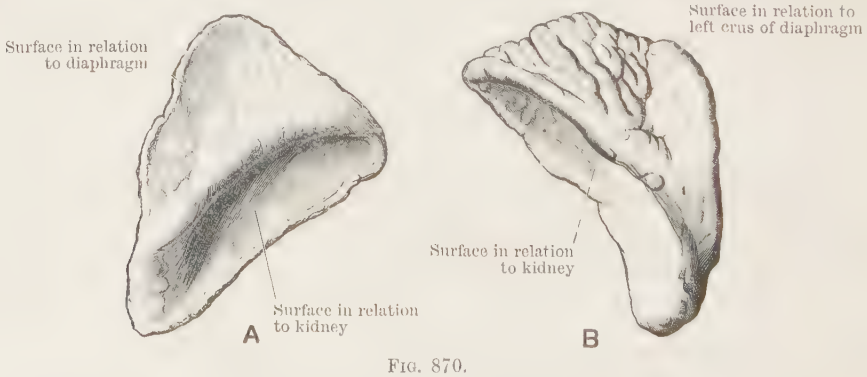

FIG. 870.

A. Posterior surface of right suprarenal capsule. B. Posterior surface of left suprarenal capsule.

part, which is applied to the diaphragm, and a concave lower part, which is occupied by fat and rests upon the kidney.

The **left suprarenal capsule** presents a semilunar form, and as a rule is slightly larger than the right capsule. Its position on the kidney is also somewhat different. It is usually placed on its inner border immediately above the hilum. The *anterior surface* presents, not far from its lower end, a very obvious slit or **hilum** with a large emerging vein. The greater part of this surface is in relation to the

posterior aspect of the stomach, and forms a portion of the bed on which that organ lies. This gastric area of the suprarenal capsule is clothed by peritoneum derived from the lesser sac. The lower portion of the anterior surface is covered by the pancreas and crossed by the splenic vessels, and is not in relation to the peritoneum. Sometimes the spleen extends inwards so as to lie in relation to the upper part of the anterior surface of the left suprarenal capsule, but this cannot be said to be the rule. The *posterior surface* is subdivided into two areas, as on the right side, by a curved ridge. The upper area is flat, and applied to the left crus of the diaphragm; the lower area is hollowed out, and is in relation to the kidney, a considerable amount of fat intervening.

In the fœtus the suprarenal capsules are relatively very much larger than in the adult. Indeed, on the left side the capsule extends downwards on the kidney so far that the spleen is completely shut out by it from that organ.

**Vessels of the Suprarenal Bodies.**—Each capsule receives three arteries—viz. from the inferior phrenic, from the aorta, and from the renal artery. One large vein, emerging from the hilum on

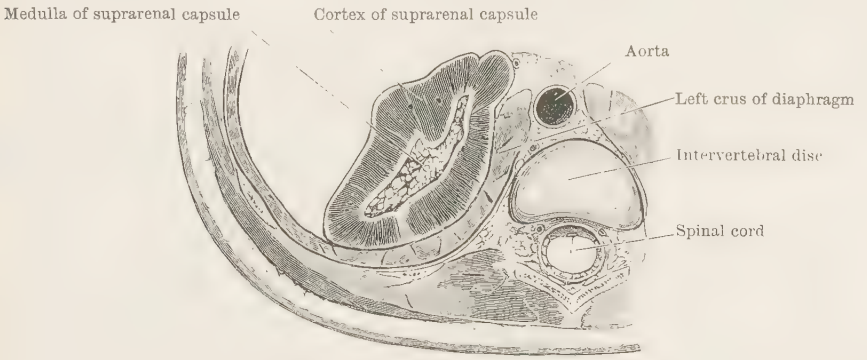

Fig. 871.—Transverse Section through the Suprarenal Capsule of a New-born Child *in situ*.

the anterior surface, as a rule conveys all the blood from the organ. On the right side it opens at once into the inferior vena cava, and on the left side into the left renal vein.

The **nerves of the suprarenal bodies** are very numerous. They come from the solar plexus, and constitute the suprarenal plexus.

**Structure of the Suprarenal Capsule.**—The suprarenal capsule is surrounded by a thin connective tissue sheath, from the deep surface of which fine processes are given off which enter the substance of the organ, and form within it a supporting stroma or framework.

The gland-substance is composed of—(1) an external cortical portion, firm in consistence, of a yellowish hue, and forming the chief bulk of the organ; and (2) an internal medullary part, very soft and pulpy, and dark brown in colour. In the bulky organ of the fœtus the appearance presented by these constituent parts is very different. The cortex is dark purple in colour, whilst the medulla presents a light yellow tint (Fig. 871).

The **cortical substance** (substantia corticalis) consists of groups of cells occupying the interstices of the stroma. These cell-groups present different forms at different levels from the surface. Thus, subjacent to the connective tissue sheath, there is a thin stratum, termed the *zona glomerulosa*, in which the cell-masses are more or less rounded; next comes the *zona fasciculata*, which constitutes the chief part of the cortex, and in which the cells are grouped in long columns which are arranged radially with reference to the surface; and lastly, there is the deepest layer, the *zona reticularis*, in which the cells are disposed in a reticular manner amidst the stroma.

The **medullary part** (substantia medullaris) is also pervaded by a fibrous stroma continuous with that of the cortex. This forms an irregular meshwork, the spaces of which are occupied by cells of very variable shape. When treated with chromic salts they assume a dark brown colour, and have consequently been termed *chromaffin* or *chromogenic cells*.

The arteries enter the cortex and break up into capillaries which are arranged around the cell-groups. In the medulla there are large thin-walled capillaries into which the whole blood of the organ passes. These capillaries are closely surrounded by the medullary cells. Proceeding from them are the radicles of the capsular vein.

**Development of the Suprarenal Capsule.**—It would appear that the cortical and medullary parts of the suprarenal body have a totally different origin. The **medulla** is derived as a mass of cells which grows out from the ganglia of the sympathetic cord, and becomes in the process of development encapsulated within the cortex. It is important to note in this connexion that a certain number of chromaffin cells are found within the sympathetic ganglia. Although nervous in its origin, the medulla of the suprarenal becomes glandular and gives to the blood an internal secretion which exercises a most potent physiological action.

The **cortical part** of the suprarenal body is formed from a mass of mesodermic cells which on the right side become grouped together in the immediate vicinity of the inferior vena cava soon after that vessel is formed. The cells thus accumulated together are said to be derived directly or indirectly from the epithelial cells which line the body cavity in the region of the Wolffian ridge.

As we ascend the scale of vertebrates, the suprarenal bodies show an interesting series of evolutionary stages. "In fishes the two constituents (*i.e.* medulla and cortex) are quite separate; in amphibians they come into contact; in reptiles they are beginning to be intermixed; in birds the cortex and medulla interlace; whilst in mammals the medulla is surrounded by the cortex" (Swale Vincent).

## THE THYROID BODY.

The **thyroid body** (glandula thyreoidea) is a highly vascular, pliant structure which clasps the upper part of the trachea and extends upwards for some distance upon each side of the larynx. In size it varies greatly in different individuals, and in the female and child it is always relatively larger than in the adult male. It consists of three well-marked subdivisions—viz. two lateral lobes, joined across the middle line by the isthmus.

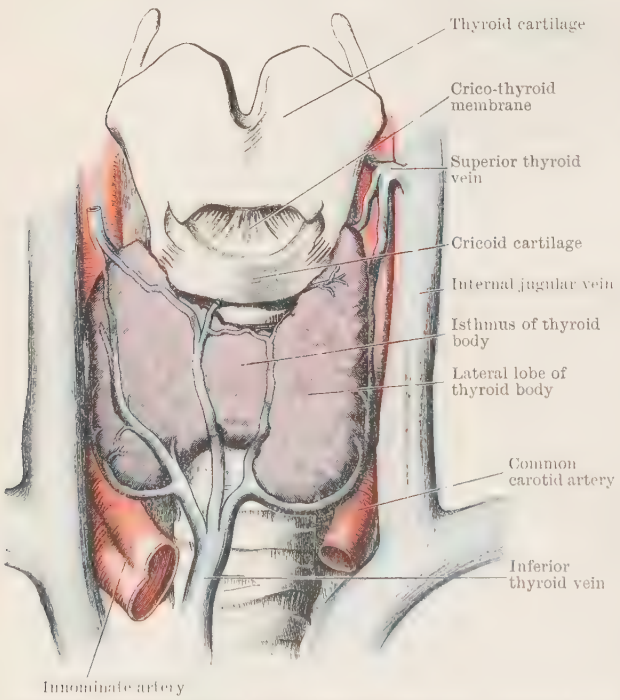

FIG. 872.—DISSECTION OF THE THYROID BODY AND OF THE PARTS IN IMMEDIATE RELATION TO IT.

Each **lateral lobe** is conical in form. Its base extends downwards upon the side of the trachea as far as the fifth or sixth tracheal ring, whilst its apex rests upon the ala of the thyroid cartilage. Its *superficial surface* is somewhat flattened, and is clothed by the pretracheal layer of cervical fascia, from which the organ derives a sheath, and also by the sterno-thyroid, sterno-hyoid, and omo-hyoid muscles. It is also overlapped by the sterno-mastoid muscle. Its *deep surface* is adapted to the parts upon which it lies—viz. to the side of the trachea, to the cricoid cartilage, and to the inferior cornu and adjoining part of the surface of the ala of the thyroid cartilage; whilst its *posterior border* extends backwards so as to touch the œsophagus and pharynx and overlap the common carotid artery (Fig. 694, p. 974).

The **isthmus** of the thyroid body is a narrow band of varying width which lies in front of the second, third, and fourth rings of the trachea, and unites the bases or lower ends of the two lateral lobes.

A third lobe is frequently found in connexion with the thyroid body. This is the **pyramidal** or **middle lobe** (Fig. 873). When present it assumes the form of an

elongated slender process which springs from the upper border of the isthmus on one or other side of the mesial plane (more usually on the left side) and extends upwards for a variable distance towards the hyoid bone upon the cricoid and thyroid cartilages. A strand of fibrous tissue, or perhaps a narrow slip composed of muscular fibres (levator glandulæ thyreoideæ), connects it to the body of the hyoid bone.

The thyroid body is firmly attached to the parts on which it lies, and therefore follows the larynx in all its movements.

**Variations.**—Small detached portions of the thyroid tissue placed in the neighbourhood of the lateral lobes or in the vicinity of the hyoid bone are not uncommon. Such glandular masses are termed **accessory thyroid bodies.** The isthmus is the part of the organ which is most subject to variation. Its size differs greatly in different individuals, and it not infrequently happens that it is absent.

**Blood-vessels.**—Four large **arteries,** and occasionally a fifth smaller vessel, convey blood to the thyroid body. Two **superior thyroid branches** spring from the external carotid arteries. Each of these divides at the apex of the lateral lobe into three branches for its supply. Two **inferior thyroid branches** from the thyroid axes of the subclavian arteries distribute their terminal branches to the basal portions and deep surfaces of the lateral lobes. The occasional artery is the **thyroidea ima,** a branch of the innominate, which ascends upon the trachea to reach the isthmus of the thyroid body. The thyroid arteries anastomose freely with each other.

The **veins** which drain the blood from the thyroid body are still more numerous. They are three in number on each side—viz. the **superior** and **middle thyroid veins,** which join the internal jugular; and the **inferior thyroid,** which descends in front of the trachea and joins its fellow of the opposite side to form a large common stem which opens into the left innominate vein. Numerous large veins ramify on the surface of the organ and lie in grooves in its substance. It is from this plexus that the inferior thyroid veins take origin.

The **nerves** which go to the thyroid body accompany the vessels. They are derived from the middle and inferior cervical ganglia of the sympathetic.

**Structure of the Thyroid Body.**—The thyroid body is enveloped by a closely-applied thin capsule of connective tissue. From the deep surface of this numerous processes penetrate into the substance of the organ, and divide it into lobes and lobules. From the septa which separate the lobules fine lamellæ proceed which form the boundaries of vast numbers of closed vesicles or alveoli of different sizes and shapes. Some of the vesicles are spherical or polyhedral, whilst others are oval or flattened and branching. All are lined by a layer of cubical or columnar epithelial cells, and most of them contain a viscid semi-fluid colloid material.

The blood-vessels traverse the organ in the fibrous-tissue septa, whilst the capillary network is disposed on the outer surface of the various vesicles. Numerous lymphatic vessels arise external to the alveoli, and Baber has shown that they frequently contain colloid material similar to that in the interior of the vesicles.

**Development of the Thyroid Body.**—The thyroid body is formed from three originally separate and distinct rudiments which arise independently of each other—viz. a median rudiment and two lateral rudiments.

The **median thyroid rudiment** arises as a hypoblastic outgrowth from the floor or ventral wall of the pharynx (Fig. 30, F.C, p. 36). The point at which this occurs is in front of the second visceral arches, at the junction between the basal portion of the tongue and that part of the organ which is developed from the tuberculum impar (see pp. 37 and 1013). The foramen cæcum on the dorsum of the adult tongue represents the upper persistent part of the median thyroid diverticulum. The median thyroid rudiment extends downwards towards the front of the larynx. It rapidly elongates, and its distal extremity bifurcates and comes to lie in front of the upper part of the trachea. This bifurcated extremity forms the isthmus of the thyroid body, and also a portion of each lateral lobe.

The portion of the diverticulum which intervenes between the dorsum of the tongue and the isthmus is termed the **thyro-glossal duct.** As already explained, its upper end persists as the *foramen cæcum* of the tongue. Its opposite extremity is usually retained as the *pyramidal lobe* of the thyroid body, whilst the intervening portion disappears. Such is the usual course of development, but in certain cases more or less extensive sections of the thyro-glossal duct may persist. The rare occurrence of a *lingual duct* which extends downwards through the tongue towards the hyoid bone is accounted for in this manner. Thyro-glossal cysts situated in any part of the path of the duct owe their origin to a similar cause.

The **lateral thyroid rudiment** of each side arises as a saccular hypoblastic diverticulum from the pharyngeal side of the fourth visceral cleft (see p. 35). It comes into relation with the lateral aspect of the larynx, and becoming cut off from the cavity of the pharynx,

it joins with the isthmus or median rudiment to form the greater part of the lateral lobe of the thyroid body.

The thyroid body in its primitive condition, and in each of its three parts, is epithelial. Soon it is invaded by connective tissue and blood-vessels, but the hypoblastic epithelium is retained as the cellular lining of its constituent vesicles.

## Parathyroids.

The **parathyroid glands** are two minute structures which lie in more or less close relation to each lateral lobe of the thyroid body. They are apt to be mistaken for accessory thyroids, but in structure they are different. One, more constant in position than the other, is situated on the posterior aspect of the œsophagus at the level of the lower border of the cricoid cartilage, and in more or less intimate relation to the posterior border of the lateral lobe of the thyroid body. The second parathyroid body is placed either in close apposition with the lower border of the lateral lobe of the thyroid, or on the trachea at a varying distance below it. The inferior thyroid artery intervenes between the two parathyroid bodies (Welsh).

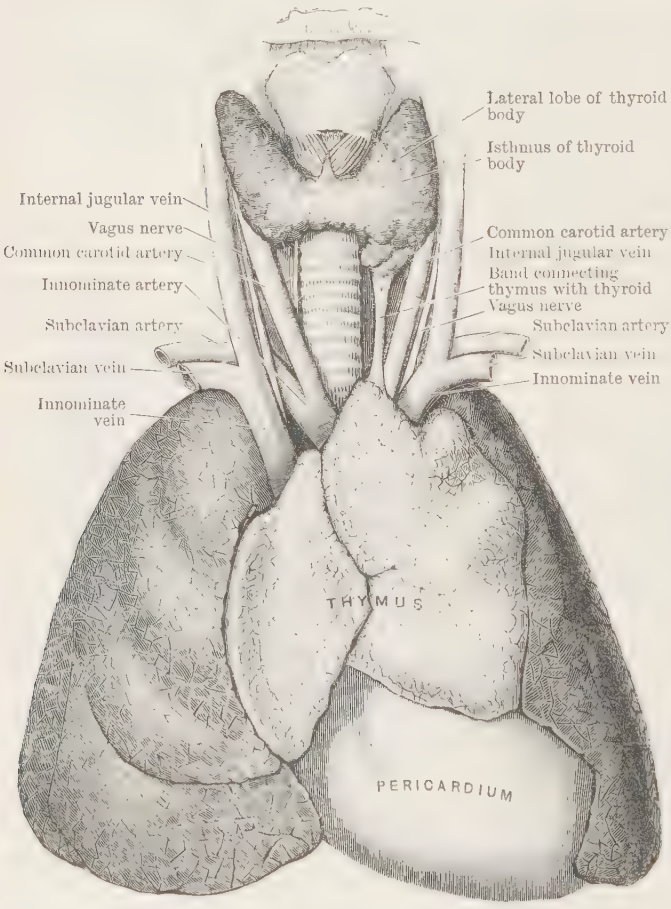

Fig. 873.—Thymus Gland in a Full-time Fœtus hardened by Formalin-injection.

The parathyroid bodies are composed of reticulating rows of cells, with blood-vessels arranged between them. In structure they bear a close resemblance to that of the anterior lobe of the pituitary body. The upper parathyroid body is derived as a hypoblastic bud, which grows out from the bottom of the pharyngeal side of the third visceral cleft; the lower body has a similar origin from the fourth visceral cleft.

It has been shown that the removal of the four parathyroids from the cat is followed by very severe symptoms, and in two cases out of three death ensued in the course of a few days (Welsh).

## THYMUS GLAND.

The **thymus gland** can only be studied to advantage in the later period of fœtal life or in early childhood. It attains its maximum development towards the end of the second year, and from this time on it dwindles away until only a comparatively small portion of it is left. In the new-born child it is of a pinkish colour, and is composed of two lateral lobes, very seldom of equal size, and separated by an intervening fissure. The main portion of the gland is placed within the thorax, but the two lobes end above in two blunt prolongations which are carried upwards for a varying distance into the neck.

The thoracic portion of the thymus gland, in its fully-developed condition, is placed in the superior and anterior mediastinal spaces, and as a rule it extends downwards as far as the level of the fourth costal cartilages. The mediastinal pleura and the lung are applied to it on either side, whilst the sternum and costal cartilages are in close relation to it in front. The deep surface of the thymus is moulded upon the pericardium and upon the vessels in the front part of the superior mediastinum. Thus, when it is hardened *in situ* and removed, it presents on its posterior surface a deep pericardial concavity, with impressions on the upper part of this hollow corresponding to the pulmonary artery and vena

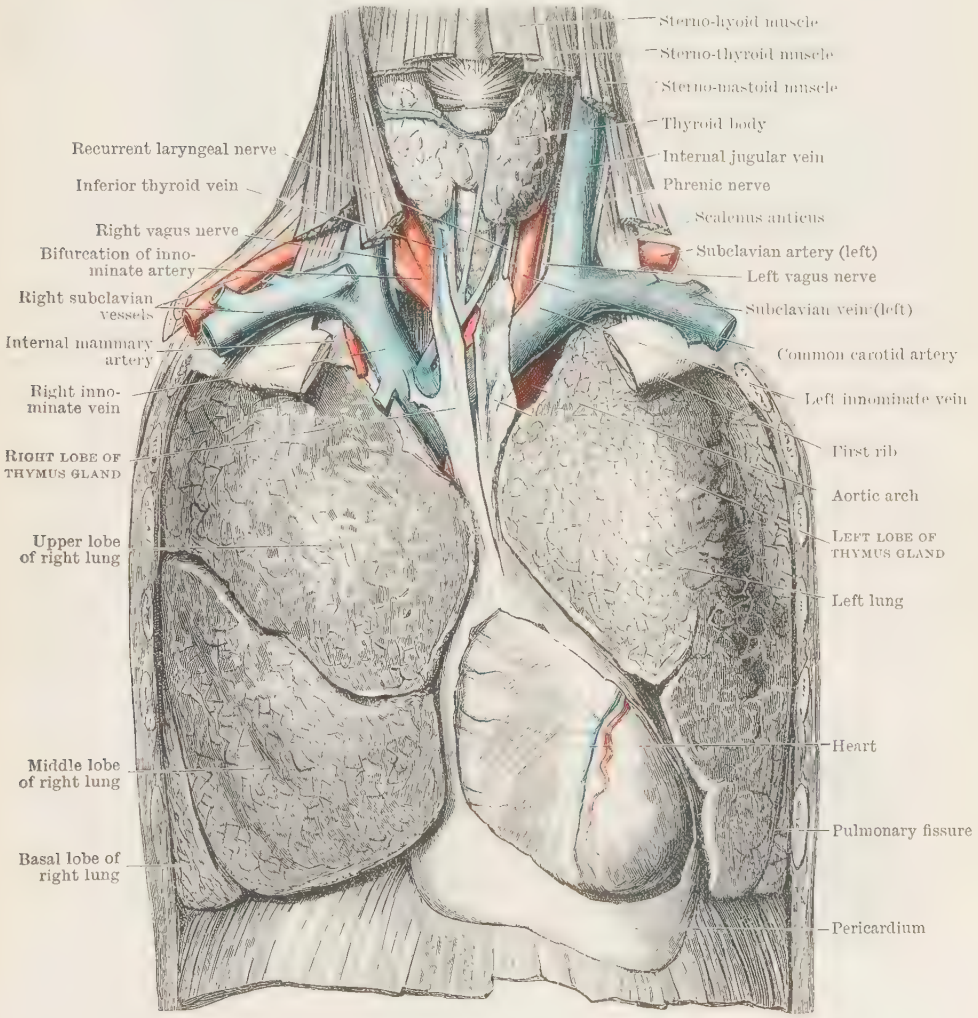

Fig. 874.—Dissection to show the Thymus Gland in an Adult Female.

cava superior (Fig. 875). Above the pericardial surface deep grooves indicate the intimate manner in which it is adapted to the two innominate veins. Above the left innominate vein the two lobes of the thymus ascend to an unequal height into the neck. They are placed in front of the trachea, and extend outwards so as to overlap the termination of the innominate artery on the right side and the left common carotid artery on the left side. One or other of the lobes may rise as high as the thyroid gland, but as a rule both fall somewhat short of this organ, and the lobe which ascends highest is usually attached to the corresponding lateral lobe of the thyroid body by a strand of connective tissue.

After the second year the thymus gland remains stationary, or it begins slowly to diminish in size, but when puberty is reached a rapid degeneration sets in. Its lobules become infiltrated with fat and loose strands of connective tissue. Waldeyer has shown, however, that throughout the whole of life it not only retains something of its old form, but also that the degeneration is never complete. Preserved within its substance (either uniformly diffused through it or in distinct masses) there may always be found remains of the original thymus-tissue. Indeed, more of the gland is retained in the adult than is generally supposed. It is easy to demonstrate in subjects hardened by formalin-injection that as a rule both lobes are present in the front part of the superior mediastinum in the form of two elongated finger-like bodies.

**Blood-vessels and Nerves.**—The **arteries** which carry blood to the thymus come from the inferior thyroid, the internal mammary, and perhaps also from other sources. The **veins** join the neighbouring venous trunks—viz. the inferior thyroid, the internal mammary, and the two innominate veins.

The **nerves** to the thymus are derived from the vagus and sympathetic trunks.

The **lymphatic vessels** are of large size, and accompany the blood-vessels.

**Structure of the Thymus.**—The thymus is composed of a large number of small polyhedral lobules. The sheath which envelops the organ sends off from its deep surface fine partitions or septa which pass into the gland and separate the different lobules from each other.

Each lobule is composed of clusters of lymphoid follicles, with a small amount of delicate connective tissue intervening between them. A follicle consists of an outer **cortical** and an inner or central **medullary portion.** Both are formed of adenoid tissue, but in the cortex the lymphoid cells are packed much more closely, whilst in the medulla the retiform matrix is coarser and the lymphoid cells less numerous. Further, the medulla contains the *concentric corpuscles of Hassall.* These are curious bodies, composed of flattened cells arranged concentrically around a granular nucleated corpuscle.

The blood-vessels form a fine plexus around the various follicles, and from this capillaries penetrate into the central medulla.

**Development of the Thymus Body.**—The thymus gland is derived from the hypoblastic lining of the pharynx. It takes origin as a tubular diverticulum from the dorsal part of the pharyngeal aspect of the third visceral cleft on each side (see p. 35). This diverticulum has thick epithelial walls, and it grows by rapid proliferation of its cells. It extends downwards on the side of the trachea towards the pericardium, and coming into contact with the corresponding hypoblastic outgrowth of the opposite side, the two lobes of the organ are formed—one from each lateral diverticulum. The narrow upper part of the outgrowth remains for a time tubular, and connected with the pharyngeal cleft from which it originates. Ultimately this connexion is broken through, and the expanded lower end sends out solid bud-like branches after the manner of an acinous gland. The connective tissue sheath and framework of the thymus are derived from the surrounding mesoblast.

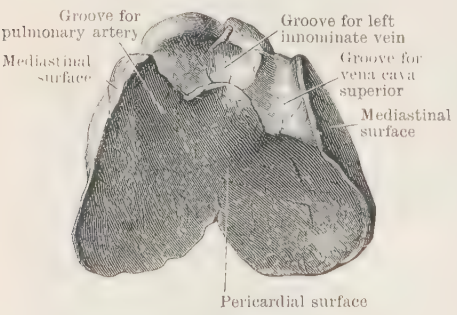

FIG. 875.—DEEP SURFACE OF THYMUS GLAND, TAKEN FROM A FŒTUS HARDENED BY FORMALIN-INJECTION.

Originally epithelial in its composition, the thymus becomes lymphoid by the rapid proliferation of its cells. The products of this division become the lymphoid cells of the follicles of the gland. The corpuscles of Hassall were formerly believed to be epithelial remnants, but this is now known not to be the case, as the transformation of the original elements of the organ into lymphoid cells is complete. The corpuscles of Hassall are derived from the repeated divisions of one cell, the products of which remain attached to each other.

## THE CAROTID AND COCCYGEAL BODIES.

The **carotid body** is a minute oval reddish-brown structure placed on the deep aspect of the common carotid artery at the point where it bifurcates into its two terminal branches. It is closely connected with the sympathetic nerve filaments which twine around the carotid vessels, and numerous minute arterial twigs

enter it. In structure the carotid body is composed of nodular masses of poly-

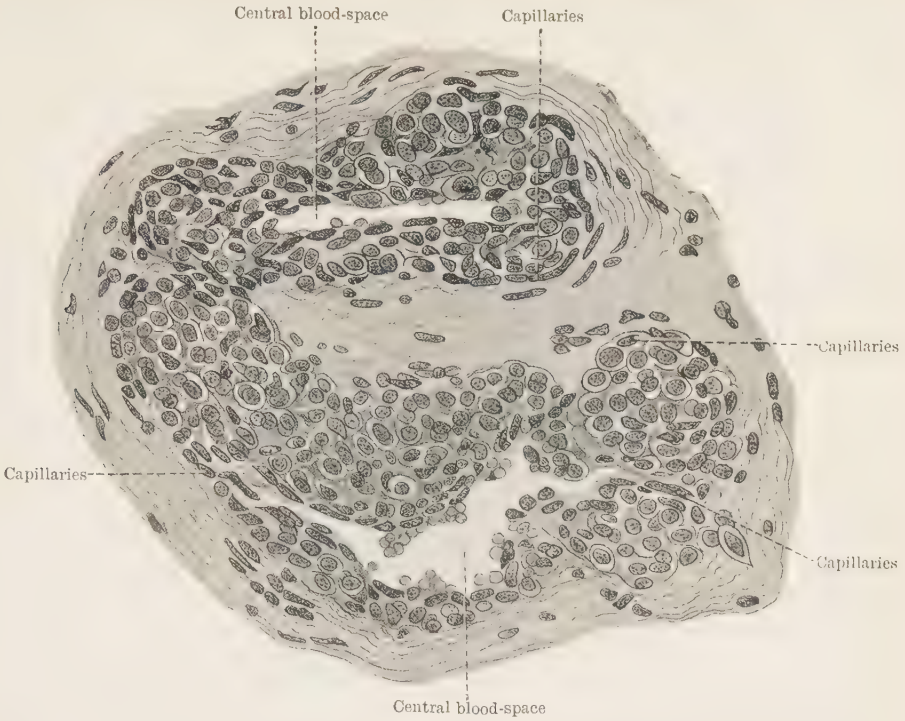

FIG. 876.—SECTION THROUGH CAROTID BODY (highly magnified). After J. W. Thomson Walker.

hedral epithelial-like cells, separated from each other by strands of connective tissue. Wide, thin-walled tortuous capillaries are brought into intimate relation with the cells.

The carotid body contains chromaffin cells, and Swale Vincent believes that it should be associated as regards both origin and function with the medulla of the suprarenal capsule.

The **coccygeal body** is a small structure placed in front of the tip of the coccyx. Branches from the middle sacral artery enter it, and its structure is similar to that of the carotid body.

Thomson Walker, who has made an exhaustive investigation into the constitution of the coccygeal gland, has shown, by means of serial sections through the region, that in addition to the main body usually described, there are numerous other minute outlying subsidiary portions of the gland grouped around the middle sacral artery and its branches. In structure the gland, as well as its accessory parts, consists of collections of round or polyhedral cells with large nuclei arranged around a central blood-space (*Archiv f. mikroscop. Anatomie*, Bd. lxiv.).

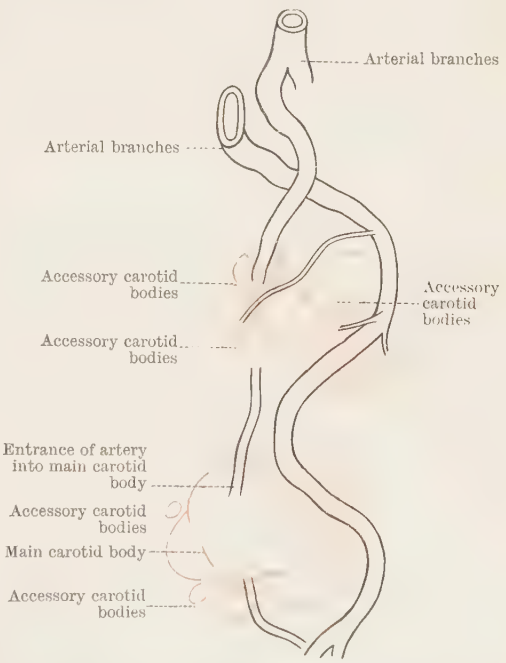

FIG. 877.—SCHEMA OF THE RELATION PRESENTED BY THE CAROTID GLAND AND ITS ACCESSORY OUTLYING PARTS TO THE BRANCHES OF THE MIDDLE SACRAL ARTERY. (Reconstructed from serial sections through the region.) After J. W. Thomson Walker.

# SURFACE AND SURGICAL ANATOMY.

By Harold J. Stiles.

## THE HEAD AND NECK.

### THE CRANIUM.

**Scalp.**—The first and third layers of the scalp, namely, the **skin** and the **occipito-frontalis muscle**, are firmly united by fibrous processes which pass from the one to the other through the second or subcutaneous **fatty layer**. Intervening between these three layers and the pericranium is a loose **cellular layer** which supports the small vessels passing between the scalp proper and pericranium. The thin **pericranium**, although regarded anatomically as periosteum, possesses very limited bone-forming properties; over the vertex it is readily separated from the skull-cap, except along the lines of the sutures, where it gives off intersutural processes to join the endosteal layer of the dura.

The free **blood-supply of the scalp** is for the purpose of nourishing its abundant hair follicles and glands. The main vessels lie in the dense subcutaneous tissue, and are superficial, therefore, to the occipito-frontalis (Fig. 878). The arteries supplying the frontal region are derived from the internal carotid, while those for the remainder of the scalp spring from the external carotid. These two sets of vessels anastomose freely with one another, and freely also across the mesial plane; hence the failure of ligature of the external carotid to cure cirsoid aneurysm of the temporal artery.

**Wounds of the scalp** bleed freely, and the vessels are difficult to ligature on account of the adhesion of their walls to the dense subcutaneous tissue. In extensive flap wounds and in diffuse suppuration beneath the occipito-frontalis there is little danger of sloughing of the scalp. **Abscesses** and **hæmorrhages** superficial to the occipito-frontalis are usually limited on account of the density of the subcutaneous tissue. Hæmorrhage beneath the occipito-frontalis is seldom extensive on account of the small size of the vessels, but suppuration in this situation may rapidly undermine the whole muscle; incisions to evacuate the pus should be made early, and parallel to the main vessels of the scalp. Extravasation of blood beneath the pericranium leads to a hæmatoma which is limited by the sutures.

The **veins** of the scalp communicate with the intra-cranial venous sinuses—(1) directly through their anastomoses with the large emissary veins, namely, the parietal, which opens into the superior longitudinal sinus, and the mastoid and posterior condyloid, which open into the lateral sinus; (2) through the anastomoses of the frontal and supra-orbital veins with the ophthalmic vein, which opens into the cavernous sinus; (3) through the veins of the diploë, which connect the veins of the scalp and the pericranium on the one hand with those of the dura mater and the venous sinuses on the other; (4) through small veins which pass from the pericranium through the bones and the intersutural membranes to the dura. It is along these various channels that pyogenic infection may extend, from the scalp and pericranium, through the bone to the dura mater and venous sinuses, and from the latter to the cerebral veins, the pia-arachnoid, and the substance of the brain. More rarely the infection spreads from the cranial cavity along the emissary veins to the scalp.

The **lymphatics** of the anterior part of the scalp join the facial lymphatics; those of the temporal and parietal regions open into the pre-auricular and parotid lymphatic glands, situated in front of and below the ear, and into the post-auricular

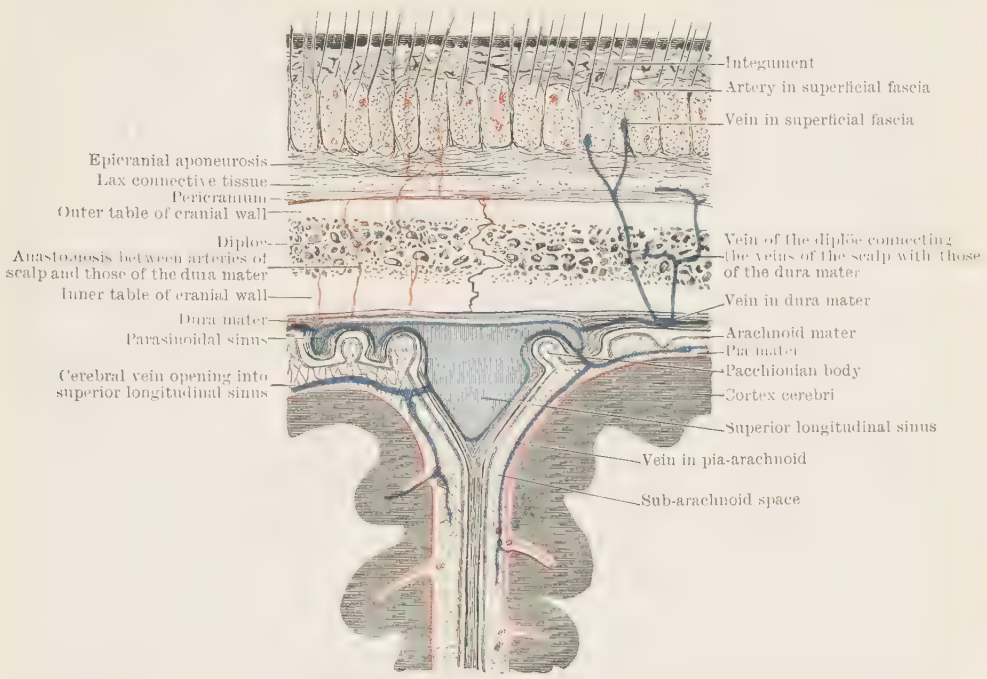

FIG. 878.—DIAGRAMMATIC REPRESENTATION OF A CORONAL SECTION THROUGH THE SCALP, CRANIUM, MENINGES, AND CORTEX CEREBRI (modified from Cunningham).

or mastoid glands, situated upon the insertion of the sterno-mastoid muscle. The lymphatics of the occipital region open into the occipital glands, which lie close to the occipital artery where it becomes superficial in the scalp.

**Bony Landmarks of the Cranium.**—At the root of the nose is the fronto-nasal suture (**nasion**); a little above it is the **glabella**, a slight prominence which connects the superciliary ridges. About 1 in. below the posterior pole of the cranium, and 2 in. above the spine of the axis, is the external occipital protuberance (**inion**). In the child the protuberance is not developed; its position may be defined by taking a point at the junction of the upper and middle thirds of a line extending from the posterior pole of the skull to the spine of the axis. About a third of the distance from the nasion to the inion is the **bregma** or junction of the coronal and sagittal sutures; with the head in the natural erect posture the bregma corresponds to the middle of a line carried across the vertex between the pre-auricular points of the zygomatic arches.

At birth the position of the bregma is occupied by the **anterior fontanelle**, a rhomboidal membranous area which generally becomes ossified at about the eighteenth month. The size and date of closure of the fontanelle, as well as its tension and pulsation, are all points to be carefully noted in the clinical examination of children.

The **lambda**, or junction of the sagittal and lambdoidal sutures, situated 2½ in. above the inion, can generally be felt through the scalp; a line drawn from it to the posterior border of the root of the mastoid process corresponds to the **lambdoidal suture**. In the adult the *parieto-occipital fissure* of the brain lies opposite, or a few millimetres in front of, the lambda; in the child, however, the fissure may be as much as 1 in. in front of it.

Crossing the supra-orbital margin close to its inner angle, a finger's-breadth from the middle line, are the **supra-trochlear nerve** and the **frontal branch of the ophthalmic artery**; the latter nourishes the flap in the operation of rhinoplasty. At the junction of the inner and middle thirds of the supra-orbital margin, 1 in

from the middle line, is the **supra-orbital notch** or **foramen**, the guide to the **supra-orbital vessels** and **nerves**. A little above the level of the outer canthus of the eyelid is the **fronto-malar suture**, immediately above which is the **external angular process** of the frontal bone. At the posterior end of the suture the **temporal branch** of the **orbital nerve** pierces the temporal fascia to reach the scalp. Half an inch above the suture is the **lower margin** of the **cerebral hemisphere**; while half an inch below the suture is a small *tubercle* on the posterior border of the malar bone; a line drawn from this tubercle to the lambda gives the line of the **parallel fissure** and of the **descending cornu** of the **lateral ventricle.**

The **zygomatic arch**, an important landmark, is horizontal when the head is in the natural position, and is on the same level as the lower margin of the orbit and the inion; its upper border is at, or not infrequently a little above, the level of the lower lateral margin of the hemisphere. The upper border of the zygoma may be traced backwards immediately above the tragus and the external auditory meatus to become continuous with the ridge formed by the **supra-mastoid portion** of the **temporal crest.** The part of the posterior root of the zygoma which lies immediately in front of the upper end of the tragus constitutes a valuable landmark which may with advantage be termed the **pre-auricular point** of the zygoma, while by the term **post-auricular point** is understood that point upon the supra-mastoid crest which lies immediately behind, and a finger's-breadth below, the upper attachment of the auricle. The **temporal vessels** and the **auriculo-temporal nerve** cross the zygoma at the pre-auriclar point, and it is here that the pulsations of the temporal artery may be felt during the administration of an anæsthetic, or the vessel compressed for the purpose of checking bleeding from the temporal region of the scalp. The termination of the auriculo-temporal nerve in the neighbourhood of the parietal eminence is often the seat of a neuralgic pain in irritative conditions about the external auditory meatus, the latter being supplied by this nerve.

Two inches vertically above the pre-auricular point is the **lower end** of the **fissure of Rolando.** Two inches vertically above the middle of the zygomatic arch is the **pterion** (spheno-parietal suture), a point which cannot be felt, but which is nevertheless of topographical importance, as it overlies the **Sylvian point** (the point where the Sylvian fissure breaks up into its three branches) and the **anterior branch** of the **middle meningeal artery.** A point three fingers'-breadth vertically above the middle of the zygomatic arch, on the left side, will mark the position of the centre of **Broca's convolution** (posterior extremity of the left inferior frontal convolution).

The **frontal eminence** (better marked in the child) overlies the **middle frontal convolution.** The **parietal eminence**, which varies considerably in the definiteness with which it can be recognised, overlies the **termination of the posterior horizontal limb** of the **fissure of Sylvius**, and therefore also the **supra-marginal convolution**, which is named by Turner the *convolution of the parietal eminence.* The part of the **temporal crest** which intervenes between the external angular process and the coronal suture lies a little above the level of the inferior frontal sulcus. The highest part of the temporal crest crosses the Rolandic area at the junction of its middle and lower thirds, that is to say, at the **junction of the motor areas for the arm and face.** In the child, the temporal muscle, which is relatively much smaller than in the adult, reaches only a short distance above the squamous suture, and, therefore, only as far as the level of the lower end of the fissure of Rolando.

The thickness of the skull-cap varies at different parts and in different individuals. The inner table is only half the thickness of the outer table, but both possess the same degree of elasticity. When the vault is fractured from direct violence, the inner table is more extensively fissured than the outer table, because the elements of the latter are compressed, while those of the former are stretched apart. The weak areas at the base of the skull through which fractures are liable to extend are: in the anterior cranial fossa, the orbital plates of the frontal bone, and the cribriform plate of the ethmoid; in the middle cranial fossa, the region of the glenoid fossa of the temporal bone, and of the foramen ovale of the sphenoid; in the posterior fossa, the cerebellar fossæ of the occipital bone. The strong petrous temporal is weakened by the tympanic cavity and by the deep jugular fossa.

**Cranio-Cerebral Topography.** — Of the many methods which have been devised for mapping out the relations of the cranial contents to the scalp, that introduced by Professor Chiene is, probably, the most useful from a clinical

point of view; no figures or angles have to be remembered, and the primary surface lines are drawn from bony points which are not variable, whilst the secondary lines are drawn, for the most part, between mid-points of the primary lines. The method is as follows (Figs. 879 and 881):—

"The head being shaved, find in the mesial line of the skull between the glabella (G) and the external occipital protuberance (O) the following points:—

"First, the *mid-point* (M); second, the *three-quarter point* (T); third, the *seven-eighth point* (S).

"Find also the *external angular process* (E), and the *root of the zygoma* (pre-auricular point) (P), immediately above and in front of the external auditory meatus. Having found these five points, join EP, PS, and ET. Bisect EP and PS at N and R. Join MN and MR. Bisect also AB at C, and draw CD parallel to AM."

The line MA corresponds to the **superior** and **inferior precentral sulci**, and may therefore be termed the *pre-central line*. The *origins* of the **superior** and **inferior frontal sulci** may be indicated by trisecting MA at the points K and L, the latter point being at the level of the temporal crest.

The line ET, termed the *oblique* or *Sylvian line*, intersects the pre-central line at the point A, which overlies the *pterion*, and corresponds therefore to the **Sylvian point** of the **fissure of Sylvius** and to the **anterior division** of the **middle meningeal artery**. AC overlies the **posterior horizontal limb** of the **fissure of Sylvius**, which terminates at the level of the temporal crest, in the lower part of the triangle HCB. This triangle contains the parietal eminence, and may, therefore, be termed the *supra-marginal triangle*. The termination of the Sylvian line, at the three-quarter sagittal point T, overlies the **parieto-occipital fissure**.

By joining TR, RO, a triangle is mapped out which delimits the outer surface of the **occipital lobe**; the line TR corresponds to the **lambdoidal suture**, while RO corresponds to, or lies a little above, the **tentorium** and the upper border of the **lateral sinus**.

CD, the *post-central line*, corresponds to the **superior postcentral sulcus**, and lies a little behind the **inferior postcentral sulcus**.

The parallelogram AMDC overlies the **Rolandic area**, *i.e.* the ascending frontal and the ascending parietal convolutions, separated by the fissure of Rolando.

The pentagon ABRPN maps out the **temporal lobe**, with the exception of its apex, which is directed downwards, forwards, and inwards, a finger's-breadth in front of the point N.

A finger's-breadth below AB is the **parallel sulcus**, the posterior extremity of which turns upwards to terminate at B, the point which indicates, therefore, the position of the **angular gyrus**.

The **fissure of Rolando** may be mapped out upon the scalp by drawing a line downwards and forwards for a distance of $3\frac{3}{8}$ in. from a point half an inch behind the mid-sagittal point M at an angle of 67° to the sagittal line (Hare). This angle may readily be found by Chiene's plan of folding a sheet of paper first to half a right angle and again to a quarter of a right angle ($45° + 22·5° = 67·5°$). According to Cunningham, the average angle which the fissure makes with the sagittal line is 70°.

The topographical distribution of function in the cerebral cortex is shown in Fig. 879, in which the areas worked out by Grünbaum and Sherrington in the anthropoid apes have been transferred to the human brain. The above observers have shown that, while the *motor area* occupies the whole length of the pre-central convolution and of the fissure of Rolando (with the exception of its very extremities), it nowhere extends on to the exposed surface of the post-central gyrus; nor does it extend as far down on the mesial surface of the hemisphere as the calloso-marginal fissure. Extirpation of the hand area, for example, is followed by severe paralysis of the hand, but the use and power of the hand is regained in a few weeks; ablations, on the other hand, of even large portions of the post-central gyrus do not give rise even to transient paralysis.

In some of the animals experimented on, the motor area was found to extend to the deeper part of the posterior wall of the fissure of Rolando. Anteriorly it

extended into the pre-central sulci as well as into the occasional sulci which cross the pre-central gyrus; indeed the hidden part of the motor area fully equals in extent that contributing to the free surface of the hemisphere. The motor areas extend a little in front of the superior and inferior pre-central sulci, which cannot therefore be regarded as physiological boundaries.

Reference to Fig. 879 shows that of the main areas that for the lower extremity occupies the upper third of the motor region, that for the upper extremity the

middle third, while the face occupies the lower third. The relative topography of the chief sub-divisions of these main areas is shown in Fig. 880. It must be remembered, however, that there exists much overlapping of the adjacent areas.

The **lateral ventricle** may be tapped or drained from above, by traversing brain tissue for a depth of 4 to 5 cm. through the superior frontal sulcus, $1\frac{1}{4}$ in. (two fingers'-breadth) in front of the point K, the instrument being directed downwards and backwards (Kocher).

Keen drains the ventricles through an opening $1\frac{1}{4}$ in. behind the external

auditory meatus and the same distance above Reid's base line (a line drawn backwards from the lower margin of the orbit through the centre of the external auditory meatus), the instrument being passed into the brain towards the summit of the opposite auricle. If the ventricle be not distended it will be reached at a depth of two inches from the surface.

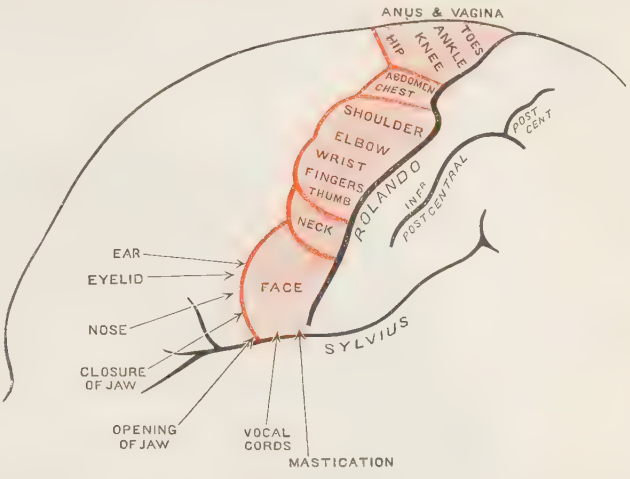

FIG. 880.—SCHEME SHOWING RELATIVE TOPOGRAPHY OF THE CHIEF SUBDIVISIONS OF THE MOTOR AREA (adapted from Grünbaum and Sherrington).

To open the **subarachnoid space**, the pin of a small trephine is placed over the mid-point of the line EA; the dura is incised as it crosses the stem of the fissure of Sylvius from the frontal lobe to the anterior extremity of the temporal lobe. Care must be taken to keep in front of the middle meningeal artery.

The **cisterna magna**, situated between the back part of the under surface of the cerebellum and the medulla oblongata, may be reached by turning down a flap of soft parts, and removing a circle of bone a little above the foramen magnum, and immediately to one side of the middle line so as to avoid the occipital sinus. The **fourth ventricle** may be opened up by making a somewhat larger trephine opening in the mesial plane and separating the posterior extremities of the tonsillar lobes of the cerebellum.

To expose the **lateral hemisphere** of the **cerebellum**, trephine over the centre of a line drawn from the tip of the mastoid process to the external occipital protuberance. The occipital artery and the mastoid emissary vein will be divided in turning down the flap.

**Meningeal Arteries.**—When the calvarium is removed the **meningeal arteries** are found to adhere firmly to the dura. Of these vessels the middle meningeal artery is the only one of surgical importance. It is frequently lacerated in fractures of the skull; the blood is generally extravasated between the dura and the bone, and the bleeding point lies beneath the clot. After entering the cranial cavity through the foramen spinosum, the *main trunk*, which is usually about 1½ in. in length, runs outward and slightly forwards to bifurcate into anterior and posterior divisions at a point a finger's-breadth above the middle of the zygomatic arch, viz. at or close behind the point N. When the main trunk is short the bifurcation takes place opposite the middle of the zygomatic arch.

The *anterior and larger division* passes upwards, with a slight forward convexity, a little behind the spheno-squamous suture and across the pterion to the anterior inferior angle of the parietal bone. From this point the vessel is continued upwards and slightly backwards behind the coronal suture; it gives off branches which ascend over the motor area. The position and general direction of the anterior branch may be said to correspond to the line LN; it follows, therefore, that the artery will be encountered in trephining over the lower and anterior part of the Rolandic area, especially over the motor centres for the tongue and face.

The *posterior division* passes almost horizontally backwards towards the posterior inferior angle of the parietal bone.

To expose the *trunk* of the vessel and its bifurcation, the trephine is applied immediately above the middle of the zygomatic arch. To expose the *anterior division* the pin of the trephine may be applied at the point A, which strikes the artery as it crosses the pterion and grooves the anterior inferior angle of the parietal

bone. The lower segment of the disc of bone removed is much thicker than the upper, as it involves the prominent ridge which passes from the tip of the great wing of the sphenoid on to the anterior inferior angle of the parietal bone. At the anterior inferior angle of the parietal bone, the artery frequently runs in a canal for a distance of half an inch. It follows, therefore, that a considerable thickness of bone has to be sawn through at the lower segment of the circle before the disc can

be removed, and during the removal bleeding may occur from the artery as it lies in the canal.

Vogt localises the *anterior division* at a point a thumb's-breadth behind the tubercle on the posterior border of the malar bone and two fingers'-breadth above the zygoma. Krönlein trephines at a point $1\frac{1}{4}$ in. behind the external angular process, on a line drawn from the supra-orbital margin backwards parallel to Reid's base line. If the centre of the trephine be placed at the mid-point of the

line LA, the anterior division will be reached above the canal and the ridge at the anterior inferior angle of the parietal; should the bleeding-point be lower down, the trephine opening may be enlarged downwards along the line LN.

The course of the *posterior division* may be indicated upon the surface by drawing a line backwards from the point N parallel to PR, that is to say, a finger's-breadth above the zygoma and the supra-mastoid crest.

When the **frontal branch** of the anterior division is injured, the clot is in the fronto-temporal region, and involves more especially the motor area for the face, and, on the left side, Broca's convolution; when the **anterior division** is wounded, the clot, which is larger, involves the parieto-temporal region, and the motor symptoms are due to pressure upon the centres for the arm and face; in injuries to the **posterior division** the clot overlies the parieto-occipital region, and the localising symptoms are sensory (Krönlein). In more extensive meningeal hæmorrhage the clot may cover the greater part of the hemisphere.

The **superior longitudinal sinus**, which enlarges as it extends backwards, occupies the mesial plane of the vertex from the glabella to the internal occipital protuberance, where it opens into the torcular Herophili, and becomes continuous usually with the right lateral sinus. Opening into the sinus, especially in the posterior part of the parietal region, are the **para-sinoidal sinuses**, into which Pacchionian glands project. In opening the skull over the posterior part of the vertex, the edge of the trephine should be kept at least three-quarters of an inch from the mesial plane.

The **lateral sinus** may be mapped out on the surface by drawing a line, slightly convex upwards, from a point a little above the level of the external occipital protuberance to the asterion ($1\frac{1}{2}$ in. behind and 1 in. above the centre of the external auditory meatus) at, or a little in front of, the point R, which forms the *highest part* of the arch of the sinus; from this point the upper border of the sinus follows the line PR for a distance of one inch, and then curves downwards and forwards to a point three-quarters of an inch below and behind the centre of the external auditory meatus, where it finally curves inwards and forwards to open into the jugular bulb, which occupies the jugular foramen. According to Moorhead the highest part of the sinus lies a finger's-breadth above the middle of a line extending from the inion to the middle of the external auditory meatus. The *anterior border* of the *descending* or *mastoid portion* of the sinus may be mapped out by drawing a line VW from a point a finger's-breadth behind the post-auricular point of the temporal crest to the anterior border of the tip of the mastoid process. In wounds of the sinus the hæmorrhage is very free, owing to the inability of its walls to collapse, but the bleeding is easily controlled by plugging.

Of the **cerebral arteries**, the *middle* supplies almost the whole of the motor area, and one of its lenticulo-striate branches, which enters the brain at the anterior perforated space, is called "*the artery of cerebral hæmorrhage*" from the frequency of its rupture in apoplexy. The extravasated blood involves the motor part of the internal capsule. The postero-mesial central branches of the *posterior cerebral* artery, which enter the brain at the posterior perforated spot, supply the optic thalamus and walls of the third ventricle; hæmorrhage from one of these branches is apt to rupture into the ventricle. The postero-lateral central branches of the posterior cerebral artery supply the optic thalamus, and when one of these vessels ruptures the hæmorrhage is apt to invade the posterior or sensory part of the internal capsule.

**Ear.**—The skin covering the outer surface of the **auricle** is tightly bound down to the perichondrium, hence inflammations of it are attended with little swelling but much pain. The **posterior auricular artery**, which ascends along the groove at the posterior attachment of the auricle, is immediately anterior to the incision for opening the mastoid antrum.

The **external auditory canal**, the general direction of which is inwards, forwards, upwards, and downwards, possesses various curves of practical importance. The highest part of the upward convexity, which is also the narrowest part of the canal, is situated at the centre of its osseous portion; beyond this the floor sinks to form a recess in which foreign bodies are liable to be imprisoned. Of the two horizontal

curves the outer is convex forwards, the inner concave forwards. The skin of the osseous portion of the canal is thin and fused with the periosteum, hence when chronically inflamed it is liable to give rise to secondary periostitis and osseous narrowing of the canal.

The relations of the osseous walls of the canal are of importance to the surgeon.

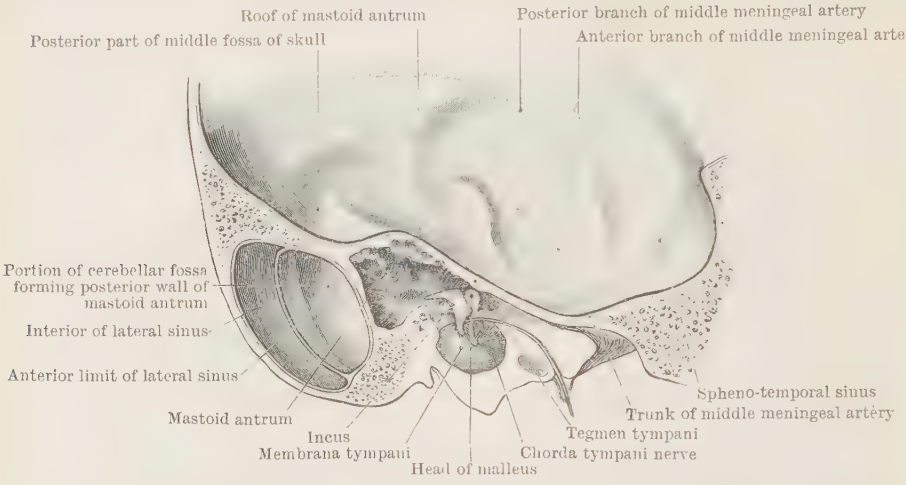

FIG. 882.—VIEW OF THE OUTER WALL OF THE MIDDLE EAR.

Section through the left temporal bone of a child, to show the relations of the middle ear and mastoid antrum to the middle and posterior fossæ of the skull.

The whole of the upper wall and the upper half of the posterior wall, developed from the squamous portion of the temporal bone, consist of two layers of compact bone, an upper and a lower, which are continuous, the former with the inner table, the latter with the outer table of the skull. The upper plate passes inwards to the petro-squamous suture, where it becomes continuous with the outer edge of the tegmen tympani, which roofs over the tympanic attic and the mastoid antrum; the lower plate bends downwards and inwards at its deepest part to form the lower and outer wall of the tympanic attic and the anterior part of the outer wall of the antrum (Trautmann). It follows, therefore, that when the mastoid antrum is abnormally small, due to sclerosis of the bone, or when it is encroached upon by a far-forward lateral sinus, it, along with the tympanic attic, can be opened by perforating the junction of the upper and posterior walls of the osseous canal, the instrument being directed inwards and slightly upwards. Upon the upper and posterior segment of the external auditory process is the **supra-meatal spine**; this small but important process, developed from the squamous portion, can usually be distinctly made out in the living subject by pressing upwards and backwards with the forefinger placed in the external auditory meatus.

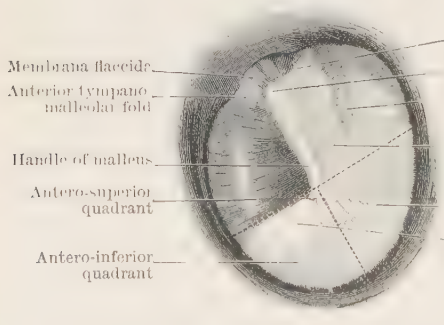

FIG. 883.—LEFT TYMPANIC MEMBRANE (as viewed from the external auditory meatus). ×3. (From Howden.)

The lower half of the posterior wall of the osseous canal (posterior part of the tympanic plate) is fused with the anterior part of the mastoid process, and closes the lower and anterior set of mastoid cells (border cells).

Anteriorly and inferiorly the osseous canal is related respectively to the **temporo-maxillary articulation** and the **parotid gland**; hence it follows that blows upon the chin may fracture the tympanic plate as well as the base of the skull, that pain on

mastication is usually complained of in acute inflammatory affections of the meatus and middle ear, and that in young children, in whom the tympanic plate is incompletely ossified, suppurative inflammation is liable to extend from the ear to the parotid region.

Clinically, to obtain a view of the **membrana tympani** a speculum and a reflecting mirror are employed; the auricle is pulled upwards, backwards, and outwards, in order to

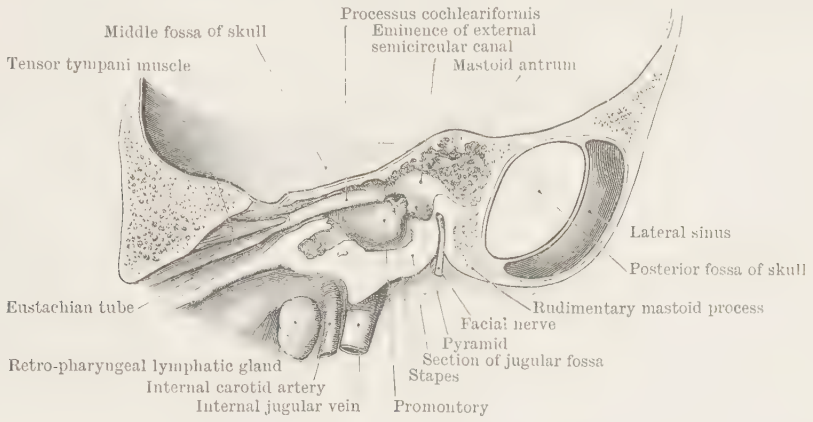

FIG. 884.—VIEW OF THE INNER WALL OF THE MIDDLE EAR.

Section through the left temporal bone of a child, to show the relations of the middle ear and mastoid antrum to the middle and posterior fossæ of the skull.

straighten the cartilaginous part of the canal. The healthy membrane is pearly gray, semi-opaque, slightly concave outwards, and obliquely placed, being inclined outwards, especially above and behind.

The handle and short process of the malleus, both embedded in the membrana tympani, are the only objects distinctly seen when the healthy ear is examined with the speculum.

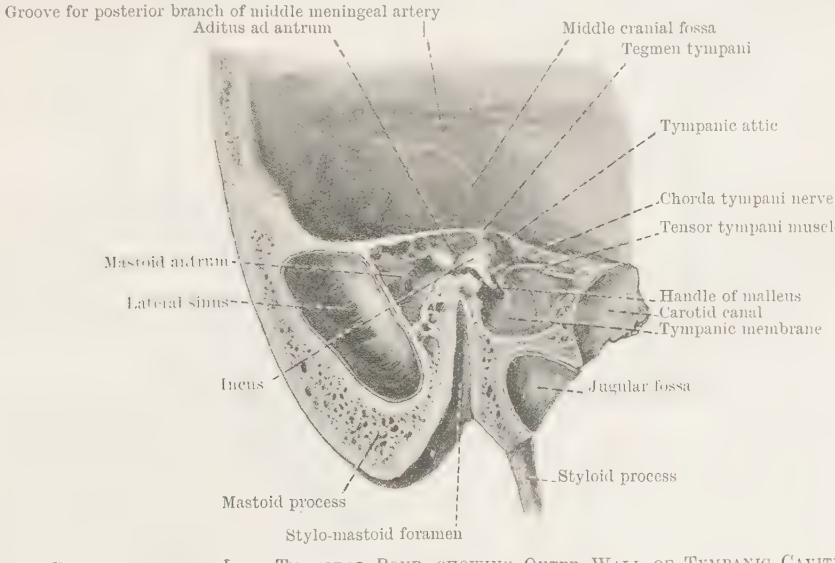

FIG. 885.—SECTION THROUGH LEFT TEMPORAL BONE, SHOWING OUTER WALL OF TYMPANIC CAVITY, ETC.

The short process of the malleus projects outwards, and presents itself, therefore, as a distinct knob-like projection at the upper part of the membrane; passing forwards and backwards from this process are the **anterior** and **posterior folds** of the **membrana tympani**; they form the lower limit of Shrapnell's membrane, and correspond to the line of the chorda tympani nerve. The handle of the malleus, situated at the junction of the two upper quadrants, is seen passing downwards and backwards to the point of maximum concavity of the membrane (umbo), situated a little below its centre (Fig. 883); passing

downwards and forwards from the umbo is the *triangular cone of reflected light*, to which too much importance must not be attached, since its appearances vary considerably in healthy ears. Normally, the long process of the incus is but faintly visible, and still less so are the promontory and foramen rotundum; in the condition of Eustachian obstruction, however, in which the membrane is indrawn, these structures, along with the folds of the drum, become more distinct.

In performing the operation of *paracentesis of the tympanic membrane* the postero-inferior quadrant is the site chosen for making the puncture, as, in addition to providing good drainage, it is farthest removed from important structures, especially the chorda tympani nerve.

In order to understand the clinical importance of the parts seen through the translucent membrane, it is necessary to study the relative position of the structure of the "*meso-tympanum*," that is to say, that part of the tympanum which lies opposite the tympanic membrane. If the tympanic plate and the tympanic membrane be carefully removed so as to leave the ossicles and chorda tympani nerve in position, it will be seen that the head of the malleus and the body and short process of the incus are altogether above the tympanic membrane, and that they occupy the **tympanic attic** or **epitympanic space** (Fig. 885). At the junction of the two upper quadrants of the membrane is the **handle** of the **malleus**, which is directed downwards, backwards, and inwards. The **short process** of the **malleus** is directed outwards a little below the deepest part of the roof of the osseous external auditory canal. Opposite the postero-superior quadrant are the **long process** of the **incus**, which descends behind and almost parallel to the handle of the malleus, and the **stapes**, which is directed inwards and slightly backwards to the foramen ovale. The **chorda tympani nerve** runs from behind forwards between the outer surface of the upper part of the long process of the incus and the inner surface of the neck of the malleus. At the deepest part of the roof of the osseous canal above the chorda tympani nerve and the short process of the malleus is a notch (*notch of Rivini*), which is occupied by the flaccid and highest portion of the membrana tympani (*Shrapnell's membrane*). Opposite the postero-inferior quadrant of the drum-head is the **promontory** of the **cochlea**, below and behind which is the **foramen rotundum**. Opposite the antero-superior quadrant are the **processus cochleariformis**, the **tendon** of the **tensor tympani**, and the passage leading towards the **Eustachian tube.**

The *inner wall* of the tympanic cavity is related to the internal ear. The *upper wall*

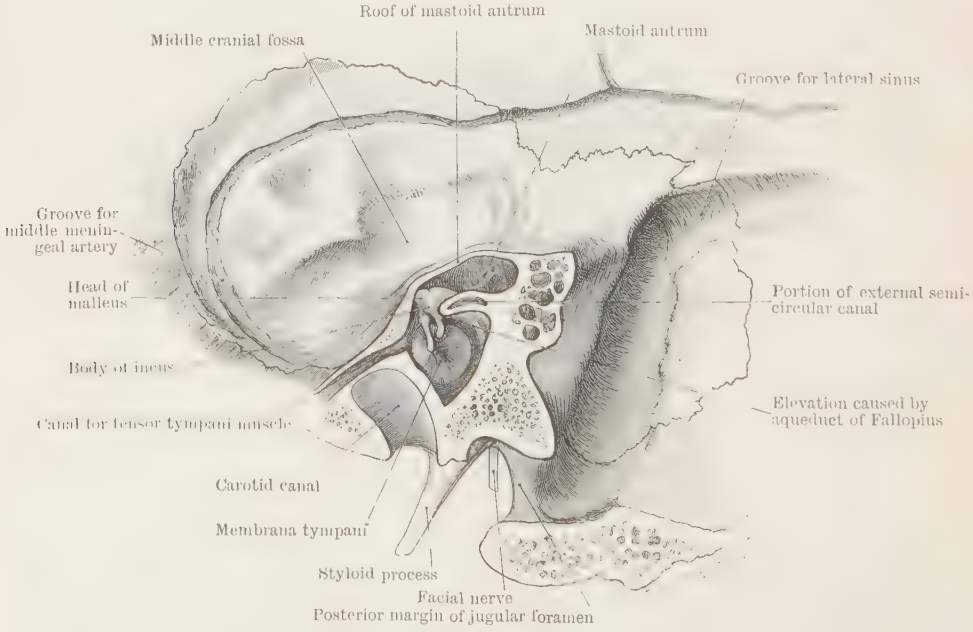

FIG. 886.—SECTION THROUGH PETROUS PORTION OF TEMPORAL BONE OF ADULT.

Showing the relation of the middle ear to the middle and posterior fossæ of the skull.

is separated from the middle fossa of the skull and the under surface of the temporal lobe of the brain by the **tegmen tympani**—a thin plate of bone, which is continued

anteriorly to form the roof of the osseous portion of the Eustachian tube, while posteriorly it roofs over the mastoid antrum. Externally the tegmen is limited by the **petro-squamous suture**, which may remain unossified for some years after birth, thus affording a channel along which pyogenic infection may spread from the middle ear to the meninges and brain. Infection may also spread along the small veins which convey blood from the tympanum to the superior petrosal and lateral sinuses.

The *floor* of the tympanum is formed mainly by the bone forming the **jugular fossa**, which is occupied by the bulb of the internal jugular vein. When the lateral sinus is large and unusually far forward the bulb is likewise large, and the fossa, which is consequently deeper, may arch up into the floor of the tympanic cavity, from which it may be separated merely by a thin and translucent plate of bone which occasionally shows an osseous deficiency. In cases where this condition existed the jugular bulb has been wounded in the operation of paracentesis of the tympanic membrane.

Anteriorly the tympanic cavity leads into the **Eustachian tube**, which brings it into communication with the naso-pharynx. In the child the Eustachian tube is shorter, wider, and more horizontal than in the adult, hence inflammations are more liable to spread along it to the tympanum.

Above the level of the membrana tympani is the **tympanic attic** or **epitympanic space**, which communicates posteriorly by means of a triangular opening (*aditus ad antrum*) with the mastoid antrum; the base of the triangle, directed upwards, is formed by the tegmen tympani; its apex, directed downwards, is formed by the meeting of the inner and outer walls. The opening will admit an instrument half a cm. in diameter. The tympanic attic contains from before backwards the head of the malleus, the body and short process of the incus, the latter projecting backwards into the aditus. When these structures are covered with inflamed mucous membrane or granulations, drainage from the mastoid antrum into the tympanum proper is interfered with. The *boundaries of the aditus*, important surgically, are as follows: superiorly, the tegmen tympani; internally, an eminence of compact bone, containing the external semicircular canal, below and in front of which is a second smaller prominence, corresponding to that portion of the aqueduct of Fallopius which curves immediately above and behind the foramen ovale. The wall of the aqueduct is here thin and not infrequently deficient, in which case inflammation may readily spread from the tympanum to the facial nerve. The outer wall of the aditus is formed by the deepest part of the upper and outer wall of the osseous external auditory canal.

The *posterior wall* of the tympanum, below the aditus ad antrum, is formed by diplöic bone which contains the descending portion of the aqueduct of Fallopius.

The **mastoid antrum** is to be considered, developmentally as well as anatomically, as an extension upwards and backwards of the tympanum (Fig. 885). Its anatomy and relations will be best understood by studying it in the child, in whom it is relatively larger than in the adult. Situated above and behind the tympanic cavity proper, its *outer wall* is formed by a triangular plate of bone which descends behind the external auditory process from the squamous portion. Posteriorly, this triangular plate is separated from the petro-mastoid element by the **petro-mastoid suture**, which overlies the posterior part of the antrum and transmits small veins to the surface. The suture does not become completely ossified until a year or two after birth, and remains of it may frequently be detected in the adult bone. The anterior and upper portion of the triangular plate turns inwards at an angle to form the upper and posterior wall of the rudimentary osseous canal, as well as the floor of the tympanic attic.

In the adult the outer wall of the mastoid antrum is formed by a plate of bone, from $\frac{1}{2}$ to $\frac{3}{4}$ in. in thickness, which occupies the triangular and somewhat depressed area between the ridge extending backwards and slightly upwards from the posterior root of the zygoma (supra-mastoid portion of temporal crest), and the upper and posterior quadrant of the osseous external auditory meatus; upon the latter is the **supra-meatal spine**, immediately behind which, upon the floor of the above triangle, is a crescentic depression, the **fossa mastoidea**. The outer wall of the antrum is felt through the skin as a slight depression immediately behind the auricle, and immediately below the ridge formed by the supra-mastoid crest; below the depression is the prominence corresponding to the insertion of the sterno-mastoid muscle. Trautmann has pointed out, however, that the supra-mastoid crest, which varies considerably in its obliquity, is sometimes situated a little above the level of the roof of the antrum, and that it is safer, therefore, to

take the level of the upper border of the osseous meatus as the guide in order to avoid opening the middle fossa of the skull. In children the supra-mastoid crest is not developed, so that if the operator mistake the posterior root of the zygoma for the crest, he will open into the middle fossa of the skull immediately in front of the attic. The upper and posterior quadrant of the osseous meatus is, therefore, the only reliable guide to the antrum in the child.

The *inner wall* is formed by a thick plate of spongy bone which separates the antrum from that portion of the posterior fossa lying between the aqueduct of the vestibule and the groove for the sigmoid portion of the lateral sinus, and which contains the posterior semicircular canal.

The *roof*, which slopes downwards and forwards, is formed by the posterior and thinnest part of the tegmen tympani.

The *floor* is on a lower level than the aditus, and is therefore unfavourably placed for natural drainage.

The **mastoid process** begins to develop in the second year. As development

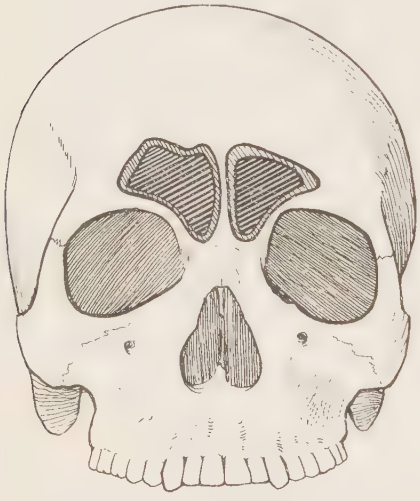

Fig. 887.—Frontal Sinuses of Average Dimensions, with a Mesial Septum (Logan Turner).

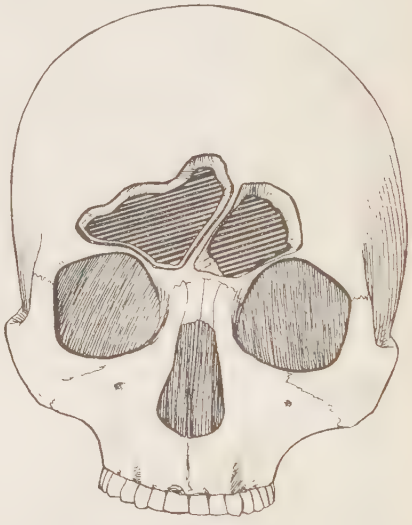

Fig. 888. — A Large Right Frontal Sinus with Septum oblique to the Left (Logan Turner).

advances the diplöe surrounding the antrum in the child becomes excavated to form the **mastoid cells**, which radiate from the antrum, and either directly or indirectly communicate with it by small openings. In the pneumatic type of mastoid the whole of the process is excavated by these cells, which extend upwards into the squamous portion, forwards to the posterior wall of the osseous meatus (border-cells), and backwards into the occipital bone. Pus retained within the "*border-cells*" may bulge into, and rupture through, the posterior wall of the osseous meatus. Less frequently the mastoid cells are absent, the bone consisting either of osseous tissue similar to that of the diplöe, or of dense bone (sclerosed type).

The mastoid process is grooved upon its inner surface by the sigmoid portion of the **lateral sinus**. The average distance of the foremost part of the sinus from the supra-meatal spine is 1 cm. The right sinus usually receives the superior longitudinal sinus, and when this is the case it is larger and farther forward than the left; in extreme cases it may reach to within 2 or 3 mm. of the meatus. The average minimum distance of the lateral sinus from the *outer* surface of the mastoid is about 1 cm., but when the sinus is large and far forward the thickness may be reduced to 1 or 2 mm.

The **facial nerve**, after entering the aqueduct of Fallopius at the bottom of the internal auditory meatus, lies immediately above and behind the foramen ovale, between it and the prominence of the external semicircular canal; thence it

descends almost vertically in the posterior wall of the tympanum $\frac{1}{8}$ in. behind and internal to the lower half of the deepest part of the posterior wall of the external osseous canal, and emerges through the stylo-mastoid foramen (Fig. 583).

*In the infant*, in consequence of the absence of the mastoid process, the exit of the facial nerve from the stylo-mastoid foramen is unprotected and exposed upon the lateral rather than upon the basal surface of the skull at a point immediately behind the posterior segment of the tympanic horse-shoe. It follows, therefore, that, in infancy, the incision to expose the antrum should not be curved too far downwards and forwards, otherwise the facial nerve may be divided. In the infant the position of the mastoid antrum is relatively higher than in the adult, because in the former the upper wall of the osseous canal inclines towards the vertical plane instead of being horizontal. The lymphatics from the auricle and external auditory meatus open into the mastoid and parotid lymphatic glands, the latter receiving also the lymphatics from the middle ear. The efferent vessels from these glands open into the superior sub-sternomastoid glands; hence it is that these groups of glands are so frequently found to be diseased secondary to tuberculosis of the middle ear; and care must be taken not to mistake an abscess in one of the mastoid glands for sub-periosteal mastoid suppuration associated with middle-ear disease.

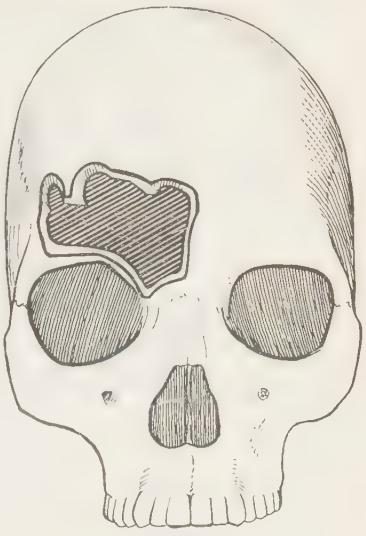

FIG. 889. — RIGHT FRONTAL SINUS OF VERY LARGE DIMENSIONS; LEFT SINUS UNOPENED (Logan Turner).

To open the **mastoid antrum** the surgeon makes a curved incision a little behind the attachment of the auricle, and chisels or drills away the bone immediately above and behind the postero-superior quadrant of the external osseous meatus. In this operation the *middle fossa* of the *skull* is avoided by keeping below the supra-mastoid crest, the *lateral sinus* by keeping close to the external auditory canal and by chiselling obliquely to the surface in opening the mastoid cells, the descending portion of the *facial nerve* is avoided by not encroaching upon the lower half of the deepest part of the posterior wall of the osseous canal. In extending the operation from the mastoid antrum through the aditus into the tympanic attic, the *external semicircular canal* and the curve of the *facial nerve*, which lie in relation to the inner wall of the aditus, are liable to injury, and must be protected either by a curved probe, or better by Stacke's protector, passed from the antrum through the aditus into the tympanic cavity.

The **frontal air sinuses** are two cavities situated immediately above the root of the nose between the two tables of the frontal bone. Each sinus at its most dependent part communicates, by means of the naso-frontal duct, either directly with the middle meatus of the nose, or indirectly with that channel through its infundibulum. A bony septum, rarely incomplete, separates the two sinuses; it is usually mesial in position below, but it may deviate to one or other side above (Figs. 887 and 888).

The sinuses vary considerably in their size and shape, independently of the degree of development of the glabella and superciliary ridges (Fig. 889). According to Logan Turner, the dimensions of an average-sized sinus are: *height*, $1\frac{1}{4}$ in., from the lower end of the fronto-maxillary suture vertically upwards; *breadth*, 1 in., from the mesial septum horizontally outwards; *depth*, $\frac{3}{4}$ in., from the anterior wall backwards along the orbital roof. The sinus may exist merely as recesses limited to a small area of bone above the nose, or it may extend upwards on to the forehead for more than two inches; externally it may be limited by the bony wall of the temporal fossa, while posteriorly it may reach as far back as the optic foramen. The anterior wall is thickest, but the thickness may vary from 1 to 5 mm. The floor is the thinnest wall, hence when pus is retained within the

cavity, it tends to point at the upper and inner angle of the orbit. Intracranial suppuration may arise in connexion with sinus disease by extension through the

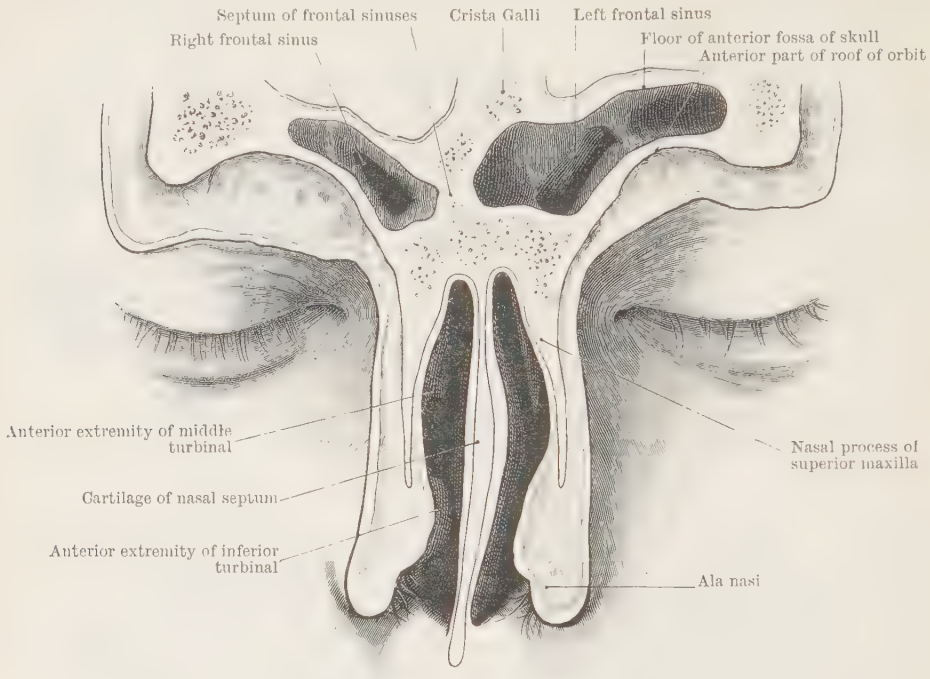

FIG. 890.—VERTICAL CORONAL SECTION THROUGH THE NOSE AND FRONTAL SINUSES.

posterior wall. The muco-periosteal lining, which readily strips from the bone, is thin and pale, and provided with mucous-secreting glands.

In many individuals, by the aid of *trans-illumination*, the extent of the sinuses and the position of the intervening septum may be mapped out upon the forehead. For this purpose a small electric lamp is placed against the floor of the sinus, beneath the inner third of the supra-orbital margin. In exploring the sinus, the opening in the bone should be made close to the mesial plane, immediately above the root of the nose. In marked cases of deviation of the septum one sinus may extend so far across the mesial plane of the forehead as to reduce the other to a mere slit; in such cases the surgeon may fail to open the diseased sinus when the operation is performed through the anterior wall. The sinus frequently contains incomplete partitions, which give rise to the formation of pockets and recesses usually found towards the external angle of the sinus; when dealing with chronic suppuration of the sinuses, special attention should be paid to these recesses as well as to the backward extension of the cavity along the orbital roof. The **anterior ethmoidal cells** are closely related to the thin inner or nasal portion of the floor of the sinus and its duct of exit; hence suppuration very frequently co-exists in both cavities. In some cases pus flows directly from the frontal sinus and infundibulum along the hiatus semilunaris into the maxillary antrum, which opens into the back part of the hiatus. Killian's operation for the cure of chronic suppuration in the sinus consists in the removal of its anterior and inferior walls, the supra-orbital margin being left to prevent the falling in of the eyebrow. By removing the frontal process of the superior maxilla good access may at the same time be obtained to the ethmoidal cells and free drainage established between the frontal sinus and the nasal cavity.

## THE FACE.

The skin of the face is thin, vascular, and rich in sebaceous and sweat glands; it is intimately connected with the subcutaneous tissue, in which are imbedded the facial muscles as well as the main blood-vessels. Owing to its elasticity and to the presence of the main blood-vessels in the lax subcutaneous tissue, the face is an

admirable site for plastic operations, as the flaps do not necrose in spite of considerable tension. The laxity of the tissues accounts for the marked swelling which attends œdematous and inflammatory conditions about the face. Whenever possible, incisions should be made along the line of the natural furrows and creases of the skin, so as to render the resulting cicatrix less noticeable.

The bony landmarks of the face which may be readily palpated are: the **superciliary ridges** and the **glabella**, the **nasion** (fronto-nasal junction), the **bridge of the nose**, the **osseous anterior nares** and the **nasal spine**, the **supra- and infra-orbital margins**, the **external** and **internal angular processes**, the anterior part of the **temporal crest**, the **malar bone**, the **zygomatic arch**, and the region of the **canine fossa** of the upper jaw.

Immediately below the root of the zygoma, and in front of the upper part of the tragus, is the **condyle of the jaw**. By pressing with the point of the finger upon the condyle while the mouth is being widely opened, the bone will be felt to glide forward, while the finger sinks deeply into the hollow corresponding to the **glenoid cavity**. The close relation of the first part of the **internal maxillary artery** to the inner aspect of the neck of the jaw must be kept in mind in operations calling for disarticulation or excision of the condyle. The ascending **ramus of the jaw** is sandwiched between the masseter and the pterygoid muscles, and can be removed without opening into the mouth. Passing downwards from the condyle, one can palpate the anterior and posterior borders of the ascending ramus and the **angle** and **body of the mandible**. The anterior border of the **coronoid process** is felt in front of the upper part of the anterior border of the masseter, immediately below the anterior part of the zygomatic arch.

The pulsation of the **facial artery** may be felt as the vessel crosses the lower margin of the mandible at the anterior border of the masseter, $1\frac{1}{4}$ in. in front of the angle of the jaw. To map out the course of the artery upon the face, draw a line from this point to a point $\frac{1}{2}$ in. external to the angle of the mouth, and thence to a point a little behind the ala nasi and along the side of the nose to the inner angle of the orbit. The **facial vein** lies behind the facial artery, and takes a straighter course from the inner canthus to the anterior inferior angle of the masseter. The vessel is devoid of valves, hence infective phlebitis and thrombosis are liable to spread along it to the cavernous sinus by way of the ophthalmic and pterygoid veins.

A line projected downwards from the supra-orbital notch (junction of inner and middle thirds of the supra-orbital margin) to the lower border of the mandible opposite the interval between the two lower bicuspid teeth, will cross the **infra-orbital** and **mental foramina**, the former $\frac{1}{4}$ in. below the infra-orbital margin, the latter midway between the upper and lower borders of the lower jaw. In performing the operation of neurectomy for the relief of trigeminal neuralgia, these foramina furnish the guides to the correspondingly-named branches of the fifth nerve. It should be remembered that the nerves in question, after emerging from their respective foramina, lie, in the first instance, beneath the facial muscles. The supra-orbital and infra-orbital nerves are not infrequently represented each by two branches, one of which passes through an accessory foramen situated external to the normal opening. Neurectomy of the **inferior pental nerve** is performed by trephining the ascending ramus of the jaw midway between its anterior and posterior borders, on a level with the crown of the last molar tooth, the nerve being reached as it enters the inferior dental canal: the **lingual nerve**, which lies a little anterior to the inferior dental, can be exposed through the same opening.

The **facial nerve**, after emerging from the stylo-mastoid foramen, is imbedded in the parotid gland where it is superficial to the external carotid artery; the nerve can be rolled under the finger as it crosses the posterior border of the ascending ramus of the jaw at the level of the lower margin of the tragus; incisions continued along the ramus above this point should be only skin deep if the nerve is to be avoided. To expose the trunk of the nerve an incision is made from the anterior border of the mastoid process to the angle of the jaw. Incisions upon the cheek should, whenever possible, be planned so as to run parallel with the branches of the nerve; these radiate from the lower end of the tragus. The nerve may

be paralysed by wounds of the cheek and by malignant tumours of the parotid, as also by intracranial and middle-ear lesions.

The **parotid gland** is surrounded by a fascial envelope, the strongest portion of which is continued from the deep cervical fascia over its superficial aspect to become attached to the zygoma (Fig. 716); hence abscesses in the parotid tend to burrow deeply towards the pterygo-maxillary space and the upper part of the pharynx (Fig. 897); the pus should therefore be evacuated by Hilton's method, through an early incision over the angle of the jaw. A study of the relations of the gland explains the surgical difficulties which attend its complete removal.

The **parotid duct** can be rolled beneath the finger as it crosses the masseter, rather less than a finger's breadth below the zygoma. After winding over the anterior border of the muscle it soon pierces the buccinator, and opens into the mouth opposite to the second molar tooth of the upper jaw. The duct corresponds to the middle third of a line drawn from the lower margin of the concha to a point midway between the ala nasi and the margin of the upper lip.

Superficial to the parotid and a little in front of the tragus is the **pre-auricular lymphatic gland**, which is frequently found to be inflamed in children suffering from eczematous conditions of the eyelids, face, scalp, and external ear. In opening an abscess connected with this gland care must be taken to make the incision as low down as possible, so as to avoid the parotid duct.

**Eyelids.**—The skin of the **eyelids**, more especially of the upper, is very thin and connected with the orbicularis muscle by delicate and lax subcutaneous tissue destitute of fat; hence the marked swelling which occurs in a "black eye" and in œdema of the lids. Along the anterior edge of the free margins of the lids are the eyelashes and the orifices of the sebaceous glands, suppurative inflammation of which gives rise to a "*stye*"; along the sharp posterior edge of the free margins are the minute orifices of the **Meibomian glands**. These glands, imbedded in the deep surface of the tarsal plates, are seen through the palpebral conjunctiva as a row of parallel, yellowish, granular-looking streaks. From the deep position of the glands it follows that the skin over a Meibomian cyst is freely movable, and that to reach the cyst an incision should be made through the conjunctival surface of the lid.

The **palpebral conjunctiva** is closely adherent to the ocular surface of the tarsal plates; at the fornix it is loose and contains small lymphoid follicles, which become hypertrophied in the condition known as granular conjunctivitis. The **ocular conjunctiva** is thin, transparent, and loosely attached to the sclerotic, so that in operating upon the eye a fold of the membrane can be picked up with forceps to steady the eyeball.

In inflammatory affections of the eye the state of those vessels which are visible gives important information as to the seat of the mischief. For example, in inflammation of the *conjunctiva* the posterior conjunctival vessels (derived from the palpebral arteries), scarcely visible normally, appear as a close network which fades away towards the corneal margin; these vessels move freely with the conjunctiva, and do not disappear under pressure. In superficial inflammations of the *cornea* the anterior conjunctival vessels (the most superficial of the terminal branches of the anterior ciliary arteries) are seen to spread in a freely branching manner into its superficial layers. In *iritis* and deep inflammations of the cornea there is a pink circumcorneal zone of vascular dilatation consisting of delicate straight vessels which disappear under pressure and do not move with the conjunctiva; they are the subconjunctival (episclerotic) terminations of the anterior ciliary arteries; in health they are invisible.

**Lachrymal Apparatus.** The **lachrymal gland**, situated behind the outer part of the supra-orbital margin, cannot be felt unless enlarged. By everting and raising the upper eyelid, the accessory (palpebral) portion of the gland is seen to project beneath the outer third of the fornix, in which situation also the minute orifices of the lachrymal ducts may be detected. By gently drawing downwards the lower lid, the small **punctum lachrymale** is seen situated upon a slight papillary elevation of its margin about 4 mm. from the inner canthus; the corresponding orifice of the upper lid is placed a little nearer the canthus. Normally the

puncta are directed towards, and accurately applied to, the ocular conjunctiva immediately external to the caruncle. By drawing the lids outwards the **internal palpebral ligament** is put upon the stretch, and can be felt as a narrow tense band passing transversely inwards to be attached to the nasal process of the superior maxilla. The ligament is a guide to the position of the **lachrymal sac**, which it crosses a little above its centre. Continuous with the lower end of the lachrymal sac is the **nasal duct**, which passes downwards and slightly backwards and outwards, to open into the inferior meatus of the nose, under cover of the anterior end of the inferior turbinal. The lachrymal sac and duct each measure about ½ in. in length; the latter is slightly contracted at its commencement and termination, and it is in these situations that pathological strictures of the duct are commonest. Spontaneous rupture of an abscess of the lachrymal sac almost invariably occurs just below the tendo palpebrarum; it is in this situation that the abscess should be opened, the incision being made a little external to the angular termination of the facial artery.

The **canaliculi lachrymales**, which convey the tears from the puncta to the lachrymal sac, run for the first 1-2 mm. almost vertically to the free margins of the lids, and thence parallel to them. Between the canaliculi is the **lachrymal caruncle.** In the various morbid conditions which give rise either to misdirection of the puncta or to stricture at any part of the lachrymal drainage apparatus, overflow of the tears (*epiphora*) is the chief symptom. In passing a probe along a canaliculus the instrument, in consequence of the bend upon the duct, is passed at first vertically to the margin of the lid, and afterwards parallel to it, until the point is felt to strike against the inner wall of the lachrymal sac; to pass the instrument onwards along the nasal duct the handle is rotated forwards and upwards through a quarter of a circle, and then pushed gently downwards and slightly backwards and outwards into the inferior meatus of the nose.

The **tarsal "cartilages"** are attached to the periosteum of the orbital margins by the **orbito-tarsal ligaments** which shut off the communication between the subcutaneous tissue of the eyelids and the fatty tissue of the orbital cavity. In fracture of the anterior fossa of the base of the skull involving the orbital plate, the blood extends forwards between the periosteum and the musculo-fascial envelope of the orbit and appears under the conjunctiva.

To obtain free access to the cavity of the orbit, the surgeon first enlarges the palpebral fissure by making a horizontal incision from the outer canthus to the outer margin of the orbit, and then, after everting the eyelid, divides the conjunctiva along the fornix of the upper or lower lid, or of both, as may be desired.

**Nose.**—To examine the anterior nares (*anterior rhinoscopy*) a strong light is reflected into the nostril, which is dilated by means of a nasal speculum. The **anterior extremity of the inferior turbinal** appears as a rounded body projecting from the outer wall of the nose; in turgescence of its erectile tissue it is liable to come in contact with the nasal septum and so occlude the nostril. The **inferior meatus**, situated between the inferior turbinated body and the floor of the nasal fossa, is brought into view by tilting forwards the head. The **lower aperture of the nasal duct** is concealed from view by the anterior part of the inferior turbinal. The **floor** of the nose is horizontal and placed on a slightly lower level than the anterior nares. The **septum**, generally more or less deviated to one or other side, is seen when the head is slightly rotated away from the side to be examined. The **anterior extremity of the middle turbinal**, which lies a little behind and internal to the lower-internal angle of the orbital margin, is seen when the patient's head is thrown well back; between it and the septum is a slit-like interval (*olfactory cleft*). By rotating the patient's head towards the corresponding shoulder the **anterior part of the middle meatus** is brought into view; pus in this situation may originate from the frontal, the anterior ethmoidal, or the maxillary sinuses, all of which open into the **hiatus semilunaris** of the middle meatus (Fig. 555).

To make a satisfactory *digital exploration* of the anterior part of the nasal cavities, it is necessary to divide the columella and the cartilaginous septum with a strong pair of scissors, one blade being introduced into each nostril (Kocher); blood spurts from the small arteries of the septum, but the bleeding soon ceases.

When these vessels, which are derived from the superior coronary arteries, are the source of the hæmorrhage in epistaxis, the bleeding can be arrested either by compressing the coronary arteries, by plugging the anterior nares, or by grasping the cartilaginous part of the nose firmly between the finger and thumb.

The **maxillary sinus** or **antrum of Highmore**, situated in the upper jaw, is a pyramidal cavity with its base formed by the outer wall of the nose and its apex directed towards the malar bone (Fig. 126). The cavity is lined by a thin mucoperiosteal membrane, easily separable from the bone; in the mucous layer are numerous mucous glands from which cysts may develop. The floor of the antrum, which is at or a little below the level of the floor of the nose, is separated from the roots of the bicuspid and molar teeth by a plate of bone of varying thickness. When this plate is thin and devoid of spongiosa, the floor of the antrum sinks below the level of the floor of the nose, and suppuration at the roots of one of the teeth above mentioned is in these circumstances very liable to extend to the antrum. In an antrum of average dimensions the line of union of the nasal and facial walls of the cavity corresponds externally to the outer edge of the canine ridge (Logan Turner). The *antral orifice* is situated at the highest part of the antrum, and is therefore unfavourably placed for natural drainage; it opens into the posterior and lower part of the infundibulum, which in its turn communicates with the middle meatus of the nose through the *hiatus semilunaris*. In old age there is frequently a second communication between the antrum and middle meatus, the opening being situated behind and below the normal orifice; when this accessory osteum exists, pus from the antrum may drain backwards into the naso-pharynx (Logan Turner). In *empyema of the antrum* the opening to evacuate and drain the cavity may be made (1) through the alveolus of the second bicuspid or of the first or second molar tooth, the first molar being the site of election; (2) through the canine fossa, external to the prominence caused by the root of the canine tooth; or (3) through the outer wall of the inferior meatus of the nose.

**Lips.**—In compressing the **coronary arteries**, it must be remembered that they run beneath the mucous surface of the lips a short distance from their free margins. The lips are abundantly supplied with **mucous glands** which can be felt immediately beneath the mucous membrane nearer their attached than their free borders; the glands are a frequent source of mucous cysts; occasionally they are enlarged congenitally, giving rise to one form of hypertrophy of the lip.

*Hare-lip* is due to failure of the union of the superficial parts of the internal nasal subdivision of the fronto-nasal process with the maxillary process (Fig. 891). The deformity is spoken of as complete or incomplete according as the cleft extends into the nostril or merely involves a portion of the lip. The fissure may involve the lip only, or it may include the alveolar process of the jaw; in the latter case the cleft may or may not be associated with a cleft of the palate. Lastly, the hare-lip may be single or double, according as the deficiency has occurred on one (usually the left) or both sides.

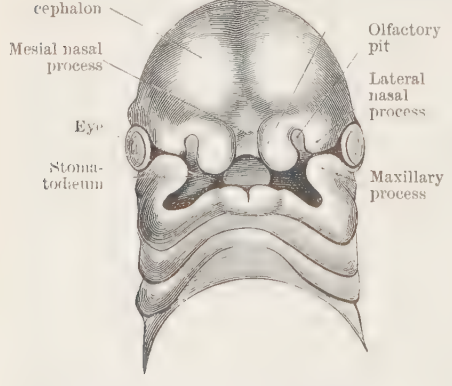

Fig. 891.—Head of Human Embryo about 29 Days old, showing the division of the lower part of the mesial frontal process into the two globular processes, the intervention of the olfactory pits between the mesial and lateral nasal processes, and the approximation of the maxillary and lateral nasal processes, which, however, are separated by the oculo-nasal sulcus (from His).

Fig. 892, taken from a coronal section through the head of a human embryo at the seventh week, shows how the mouth is shut off from the nasal cavities by the growth inwards from the deep aspect of the maxillary process of two horizontal plates (palatal processes) which unite in the middle line with each other and with the lower border of the septum of the nose; the latter, which develops as a downgrowth from the primitive basis cranii, is continuous anteriorly with the two internal nasal processes which form the premaxillæ and the middle portion of the upper lip. The various degrees of *cleft palate* are due to the more or less complete failure

of union of the palatal processes with each other and with the premaxillary part of the internal nasal processes. The cleft in the soft palate, which is always mesial, may be either partial or complete, and may or may not extend forwards into the hard palate. The cleft in the latter is spoken of as single or double according to whether the palatal processes have failed to unite with the lower edge of the nasal septum on one, or on both, sides. When the cleft extends forwards through the alveolar process to become continuous with a cleft of the lip, the inner (premaxillary) edge of the cleft is usually projected forwards in advance of the outer (maxillary) edge. Before proceeding to repair the cleft in the lip, the projecting premaxillary edge is forced back into line with the maxillary edge.

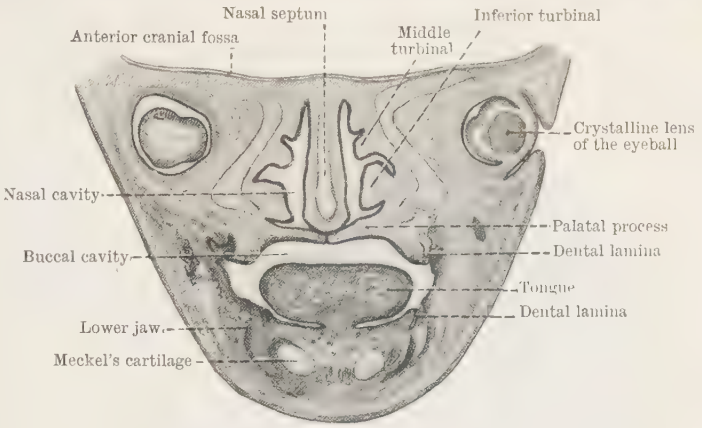

FIG. 892.—CORONAL SECTION THROUGH THE FACE OF A HUMAN EMBRYO AT THE SEVENTH WEEK.

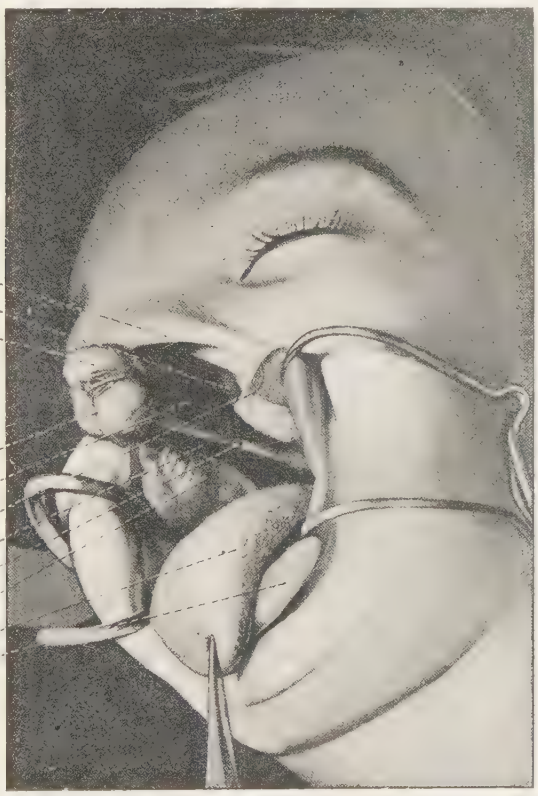

FIG. 893.—FROM A PHOTOGRAPH SHOWING DOUBLE COMPLETE HARE-LIP AND CLEFT PALATE.

In what is known as a complete double cleft palate, the palatal processes fail to join the nasal septum and the premaxillæ on both sides; the result is a wide median cleft which communicates with both nasal cavities. The free lower border of the vomer extends along the middle of the cleft to be continuous anteriorly with the rounded premaxillary mass; the latter, along with the central portion of the upper lip, is projected forwards between the two labial clefts, often to such an extent that it appears to spring from the tip of the nose (Fig. 893). In operating on such a double hare-lip the first step is to get rid of the premaxillary projection. This is done, not by removing it altogether, but by removing a triangular portion of the septum of the nose behind it, so as to allow of its being bent back into line with the alveolar processes of the superior maxillæ. The base of the triangular piece of bone should not be taken from the constricted portion of neck of the premaxillary projection, but should consist of the olive-shaped thickening situated

immediately behind the neck. This thickening is crossed by the transverse suture uniting the premaxilla with the anterior extremity of the vomer (Fig. 894). If the premaxillary projection be removed altogether, there is nothing left to support the upper lip, and the result is an ugly deformity, due to the comparative protrusion and redundancy of the lower lip.

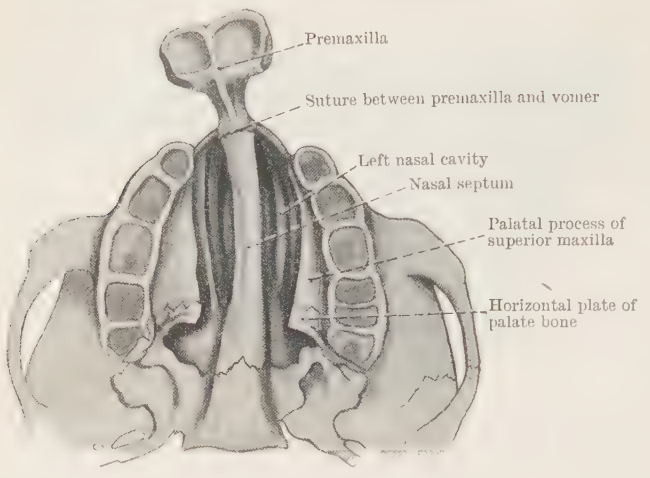

FIG. 894.—SHOWS ARRANGEMENT OF BONES IN DOUBLE CLEFT PALATE (*Handbook of Practical Surgery*, Bergmann, Bruns, and Mikulicz).

**Teeth.**—The **milk teeth** begin to appear from the sixth to the eighth month, the first to emerge being the lower central incisors. The first dentition is completed about the thirtieth month. Delayed dentition is generally due to rickets. Of the **permanent set** the first to erupt are the first molars, which appear at the end of the sixth or seventh year; the third molars (wisdom teeth), the last to appear, may erupt any time between the eighteenth and the twenty-fifth year, or even later. As the permanent teeth push their way towards the surface, absorption of the roots of the first set takes place, which either fall out of their own accord or are easily removed. Loss of the permanent teeth is followed by absorption of the alveolar margin of the jaw. The tooth sockets are lined by a thin periosteum, which is anatomically continuous with the pulp tissue of the teeth on the one hand and the dense fibrous tissue of the deep layer of the gum on the other.

The upper incisors and canines and the lower bicuspids have *cylindrical* roots, hence in extracting these teeth they should be first loosened by a slight rotatory movement; the roots of the lower incisors and canines and of the upper bicuspids are *flattened*, so that they must be loosened by a lateral movement. The roots of the wisdom teeth are *convergent*, generally welded together and curved backwards, especially in the lower jaw. The first and second upper molars have three roots which are often *divergent* (Figs. 719 and 720).

**Tongue.**—For practical purposes, as well as on developmental and structural grounds, it is convenient to divide the tongue into an anterior two-thirds—the **oro-glossus**, and a posterior third—the **pharyngo-glossus** (Wingrave). Fig. 897. At the junction of the two portions, immediately behind the median circumvallate papilla, is the **foramen cæcum**, which represents the remains of the upper or pharyngeal extremity of the **thyro-glossal tract**. *Congenital cysts* and *fistulæ* which develop from persistent remains of this tract are always mesial; those arising from the upper or lingual portion of the tract are situated above the hyoid bone, whereas those developed from the lower or thyroid portion are situated below the hyoid bone. The liability of these cysts and fistulæ to recur after operation is probably due to the fact that part of the epithelial tract lies in the substance of the hyoid bone.

The mucous membrane covering the pharyngo-glossus is much more sensitive than that covering the oro-glossus, hence in using a tongue depressor the instrument should, except under special circumstances, rest only upon the latter region, otherwise a reflex arching of the tongue will be set up, which prevents the operator from obtaining a satisfactory view of the throat. Scattered over the pharyngo-glossus are clusters of **lymphoid follicles** (lingual tonsils), which appear on the surface as a number of nodular umbilicated elevations provided with little crypts into which mucous glands open (Fig. 710). The lingual tonsils are liable to chronic inflammation and hypertrophy, conditions which are often accompanied by

a varicose condition of the veins which lie immediately beneath the mucous mem-

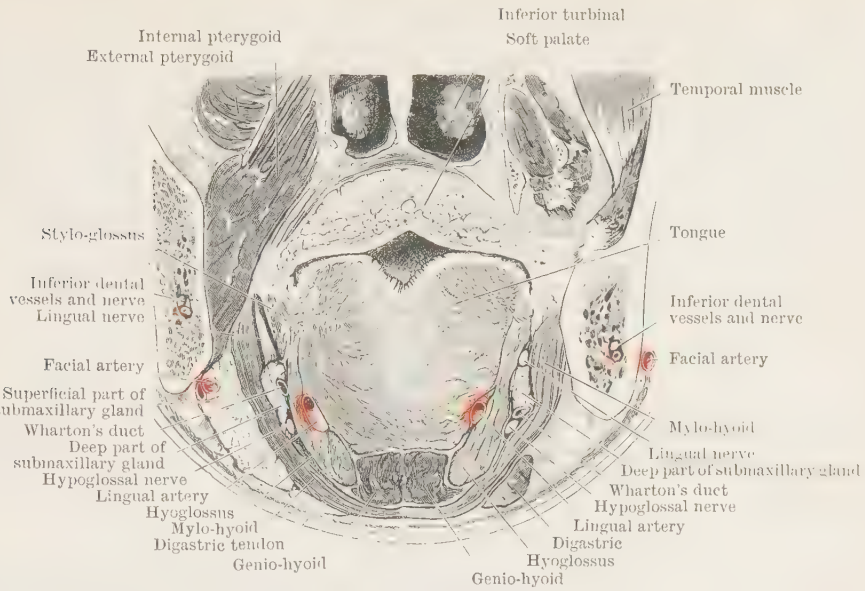

FIG. 895.—CORONAL SECTION THROUGH THE TONGUE AND SUBMAXILLARY REGION IN A PLANE BEHIND THE MOLAR TEETH (from Cunningham).

brane containing the palato-glossus muscle. To obtain a satisfactory view of the lingual tonsils in the living subject the laryngoscopic mirror must be employed.

The pair of mucous glands situated on the under surface of the tongue a little behind its tip and known as the **"apical" glands**, are of interest in that they occasionally give rise to mucous cysts similar to those which develop in connexion with the labial glands (Fig. 896).

The **muscular bundles** of the tongue are separated by a quantity of loose connective tissue, rich in blood-vessels and lymphatics (Fig. 713); hence acute inflammatory œdema of the substance of the tongue may be attended with a degree of swelling sufficient to obstruct the respiratory passage.

The main **blood-vessels** of the tongue run from behind forwards, nearer its under than its upper surface (Fig. 895); incisions into the substance of the tongue to reduce swelling and tension should, therefore, be made longitudinally upon the dorsum. Bleeding from the lingual artery, divided in the substance of the tongue, is temporarily arrested by passing the finger behind the base of the tongue and hooking it well forward, so as to

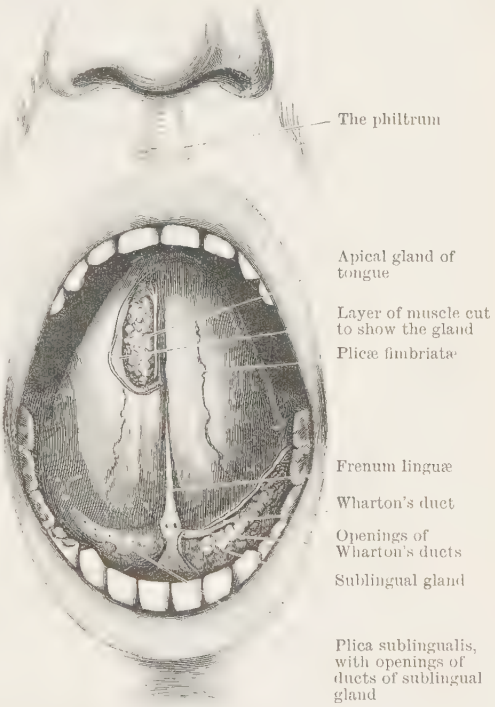

FIG. 896.—OPEN MOUTH WITH TONGUE RAISED AND THE SUBLINGUAL AND APICAL GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by removing the mucous membrane; to expose the apical gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the inner aspect of the gland. The ranine vein is faintly indicated on this side also (from Birmingham).

compress the vessel against the inner surface of the lower jaw. On account of the very slender anastomosis between the vessels of the two halves of the tongue scarcely any bleeding occurs when the organ is split mesially.

According to Poirier the collecting trunks which arise from the lymphatic networks in the mucous membrane and muscular substance of the tongue may be divided into four groups:—(1) **Apical trunks** which open partly into the submental glands and partly into a gland of the internal jugular chain lying immediately above the anterior belly of the omohyoid muscle. (2) **Marginal trunks** which pass, some external to the sublingual gland and through the mylohyoid muscle to join the most anterior of the submaxillary lymphatic glands; others pass internal to the sublingual gland, in front of and behind the hyoglossus muscle to join the glands of the internal jugular chain. The more *anterior* their lingual origin the *lower* in the chain is the gland to which they pass. (3) The **basal trunks**, from the posterior third of the tongue, pass from before backwards towards the lower extremity of the tonsils, where they pierce the superior and middle constrictors of the pharynx, and, after surrounding the lingual artery, open into a gland placed on the internal jugular vein immediately below the posterior belly of the digastric. (4) The **central trunks**, which descend in the middle line between the genio-hyo-glossi, pass beneath the hyoglossus and mylohyoid muscles into the submaxillary space, and thence in front of the hyoid bone (having embraced the tendon of the digastric) to join the glands of the internal jugular chain.

Between the tongue and the inner surface of the gums is the **alveolo-glossal sulcus**, crossed in the middle line by the **frenum linguæ**, which passes upwards to the under surface of the tongue (Fig. 896). Immediately on either side of the lower part of the frenum is the **orifice of Wharton's duct**. A little external to the frenum the **ranine veins** are seen lying immediately under the thin mucous membrane; to the outer side of the veins are the ranine arteries and the lingual nerves, both of which lie deeper than the veins, and are therefore not visible.

The mucous membrane at the anterior part of the floor of the alveolo-glossal sulcus is thrown into a slight elevation, which overlies, and is caused by, the **sublingual salivary gland**. The duct of the submaxillary gland (Wharton's duct) and the lingual nerve lie beneath and to the inner side of the sublingual gland.

In dividing a shortened frenum for "tongue-tie" the ranine vessels and the orifices of Wharton's ducts must be avoided. Behind the frenum linguæ are the anterior borders of the **genio-hyo-glossi**, which descend to the upper genial tubercles. In operations necessitating the removal of the region of the symphysis of the jaw, or the separation of the origins of the genio-hyo-glossi, the tongue must be kept forward, otherwise the patient will be suffocated by the organ falling backwards over the entrance to the larynx. In removing a small salivary calculus from the floor of the mouth the calculus should be fixed with the finger against the inner surface of the jaw before cutting down upon it.

When the teeth are clenched the vestibule of the mouth communicates behind the last molars with the oral cavity proper through an opening which barely admits a medium-sized catheter. Hence, when the jaws cannot be separated it is generally necessary to feed the patient through a tube passed along the floor of the nose.

By opening the mouth widely and taking a deep inspiration, the soft palate is elevated, and the anterior and posterior pillars of the fauces are rendered prominent (Fig. 707). The **anterior pillars** are seen to spring from the anterior surface of the soft palate, close to the base of the uvula, and to arch downwards and outwards in front of the tonsils to end at the posterior extremity of the lateral border of the tongue. The **posterior pillars** are really the continuation of the lower free border of the soft palate downwards behind the tonsils to become attached to, and lost upon, the postero-lateral wall of the pharynx. Together with the lower edge of the soft palate and the base of the tongue they bound a hemispherical opening (**isthmus faucium**), through which is visible the oral portion of the mucous membrane covering the posterior wall of the pharynx.

The **faucial tonsils** (Fig. 897) lie one on each side of the isthmus, between the anterior and posterior pillars of the fauces; they are situated opposite the angle

of the jaw, but they cannot be felt from the outside. Each tonsil is covered on its free surface by mucous membrane upon which are seen the orifices of the tonsillar crypts; the outer or deep surface is covered by a layer of fibrous tissue which forms an imperfect capsule to the organ. According to Merkel, the internal carotid artery is situated 1·5 cm. behind the outer margin of the tonsil, which is separated from the superior constrictor by a quantity of loose cellular tissue and fat, so that the gland can be grasped with a volsellum and pulled forward without dragging the vessel with it. The tonsil receives its *blood-supply* mainly from a small vessel derived from the anterior palatine artery; when

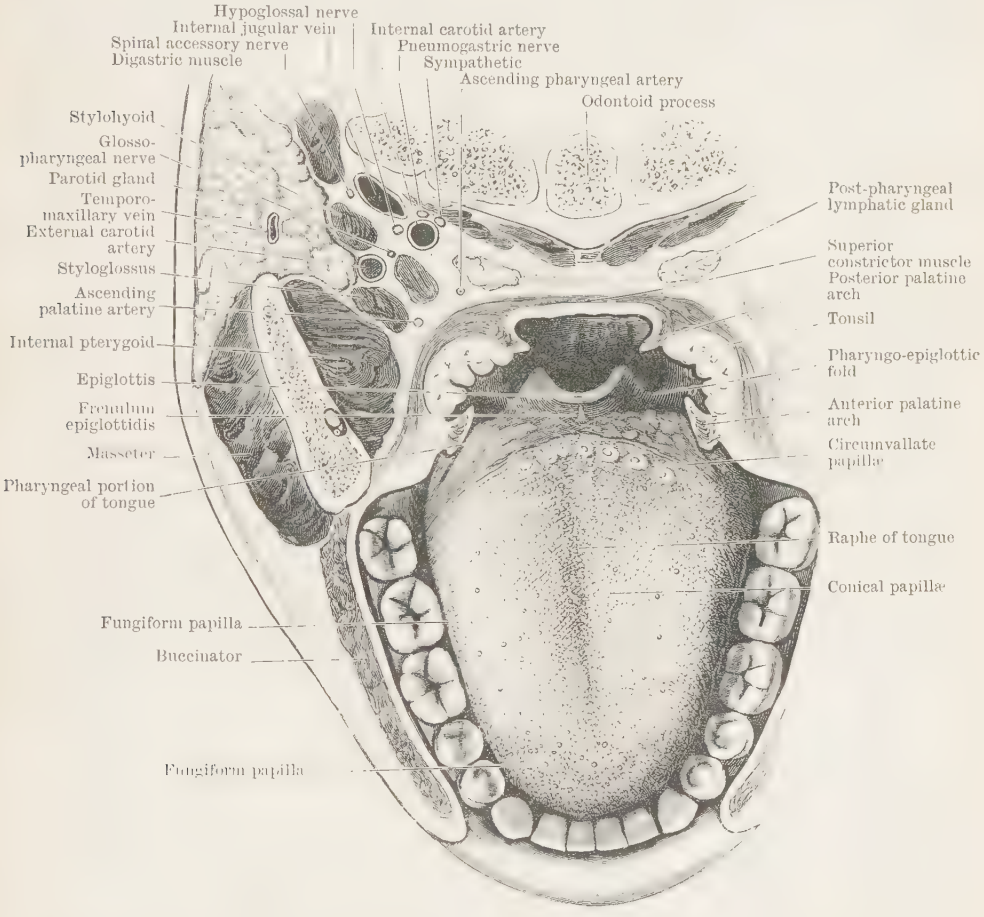

FIG. 897.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE TONSILS.

The stylopharyngeus, which is shown immediately to the inner side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines (from Birmingham).

this branch is larger than usual and adherent to the capsule of the tonsil the bleeding which attends the operation of removal of the tonsils may be considerable. The hæmorrhage can be arrested by pressing the bleeding point outwards against the internal pterygoid and the ramus of the jaw. If the bleeding be from a spurting vessel of larger size, its source, according to Merkel, is probably the *facial artery*, which has been wounded as it arches upwards beneath the digastric and stylo-hyoid muscles to within a short distance from the outer surface of the tonsil. In children and adolescents the tonsils are frequently hypertrophied; the enlargement may be either general, more towards the middle line, downwards along the pharynx, or upwards behind the soft palate; to expose and thoroughly remove the last-mentioned variety of enlargement the upper part of the anterior pillar of the fauces must be divided.

The mucous membrane and the periosteum of the **hard palate** are so closely

united as to form practically one membrane. The **posterior palatine arteries**, after leaving the posterior palatine foramina, run forward in shallow grooves in the hard palate, close to its alveolar margin. In the operation for cleft palate (*staphylorraphy*), in order to secure nourishment for the muco-periosteal flaps, the lateral incisions should be made *external* to these vessels.

Secondary hæmorrhage after the operation for cleft palate is treated by plugging the **posterior palatine foramen**, which lies a little internal to the last molar tooth about $\frac{1}{3}$ in. in front of the hamular process, which can be felt at the upper extremity of the fold of mucous membrane containing the pterygo-maxillary ligament. In the closure of a wide cleft of the soft palate the tension of the **tensor palati muscle** is got rid of by chipping off the **hamular process** with a small chisel introduced at the posterior extremity of the lateral relief incisions.

**Naso-pharynx.**—To explore the upper or nasal division of the pharynx the finger should be hooked upwards behind the soft palate. *Anteriorly*, the finger readily detects the sharp posterior border of the vomer, the posterior nares, and the posterior extremity of the middle and inferior turbinals. The *roof* of the space is formed by the basilar process of the occipital bone, while upon the *posterior wall* is a transverse bony ridge caused by the projection of the anterior arch of the atlas. Upon the *lateral walls* of the naso-pharynx are the openings of the **Eustachian tubes**, situated $\frac{1}{2}$ in. behind the posterior extremities of the inferior turbinals (Fig. 708). The orifices, bounded superiorly and posteriorly by a prominent margin, are directed downwards and forwards, and, therefore, in a direction favourable to the passage of the Eustachian catheter. Behind the prominent posterior margin of the orifice is a lateral recess of the pharynx known as the **fossa of Rosenmüller**, in which the point of the Eustachian catheter is apt to become engaged. Upon the roof and posterior wall of the pharynx, down to the level of the anterior arch of the atlas, and extending laterally as far as the Eustachian orifices, is a collection of adenoid tissue, the **pharyngeal tonsil**. Hypertrophy of this tissue constitutes the condition known as "*adenoids*," the harmful effects of which are due to their interference with nasal respiration. Upon the centre of the pharyngeal tonsil is an orifice leading into a small recess into which numerous mucous glands open. The structures felt in the post-nasal space may be rendered visible by reflecting the light upon a small mirror placed immediately behind and below the soft palate (*posterior rhinoscopy*). The lower part of the inferior turbinal is obscured from view by the bulging of the upper surface of the soft palate.

In *plugging the posterior nares*, it is important to remember that these openings measure nearly one inch in the vertical and half an inch in the transverse direction. In the child, owing to the small size of the face, the vertical diameter of the naso-pharynx is relatively much smaller than in the adult.

The **lymphatics** from the nasal fossæ and pharynx, including the faucial and pharyngeal tonsils, join the sub-parotid and upper deep cervical glands, one of which lies internal to the carotid vessel between the lateral recess of the pharynx and the prevertebral fascia. In children suppuration originating in this gland is the commonest cause of a retro-pharyngeal abscess.

In the *adult* the four upper cervical vertebræ can be explored from the mouth, while in the *child* the finger can also reach as far down as the sixth vertebra and the back of the cricoid cartilage.

## THE NECK.

The general envelope of **deep cervical fascia**, along with the processes and partitions which proceed from its deep surface, subdivides the neck into compartments which limit and determine the spread of pus. The most important compartment is the **central** or **visceral compartment**, bounded *anteriorly* by the pretracheal fascia, *posteriorly* by the prevertebral fascia, and *laterally* by the fascia forming the vascular compartment. Posteriorly, this compartment extends from the base of the skull downwards into the posterior mediastinum; anteriorly, it extends from the hyoid bone into the anterior part of the superior mediastinum. *Abscesses* in the visceral

compartment are either secondary to disease of the organs it contains, or the result of a primary suppurative cellulitis. A tubercular abscess originating in one of the retropharyngeal lymphatic glands (Fig. 897) lies *in front of* the prevertebral fascia, and points towards the posterior wall of the pharynx; abscesses secondary to disease of the cervical vertebræ lie *behind* the prevertebral fascia, and spread laterally behind the vascular compartment; they point behind the sterno-mastoid, and should be opened through an incision at the posterior border of the muscle, the surgeon keeping to the anterior aspect of the transverse processes in order to avoid the structures in the vascular compartment (Chiene).

In front of the visceral compartment is a **small muscular compartment** containing the depressor muscles of the hyoid bone; anterior to it again, in the region of the supra-sternal notch, is the small **supra-sternal compartment**, containing the lower

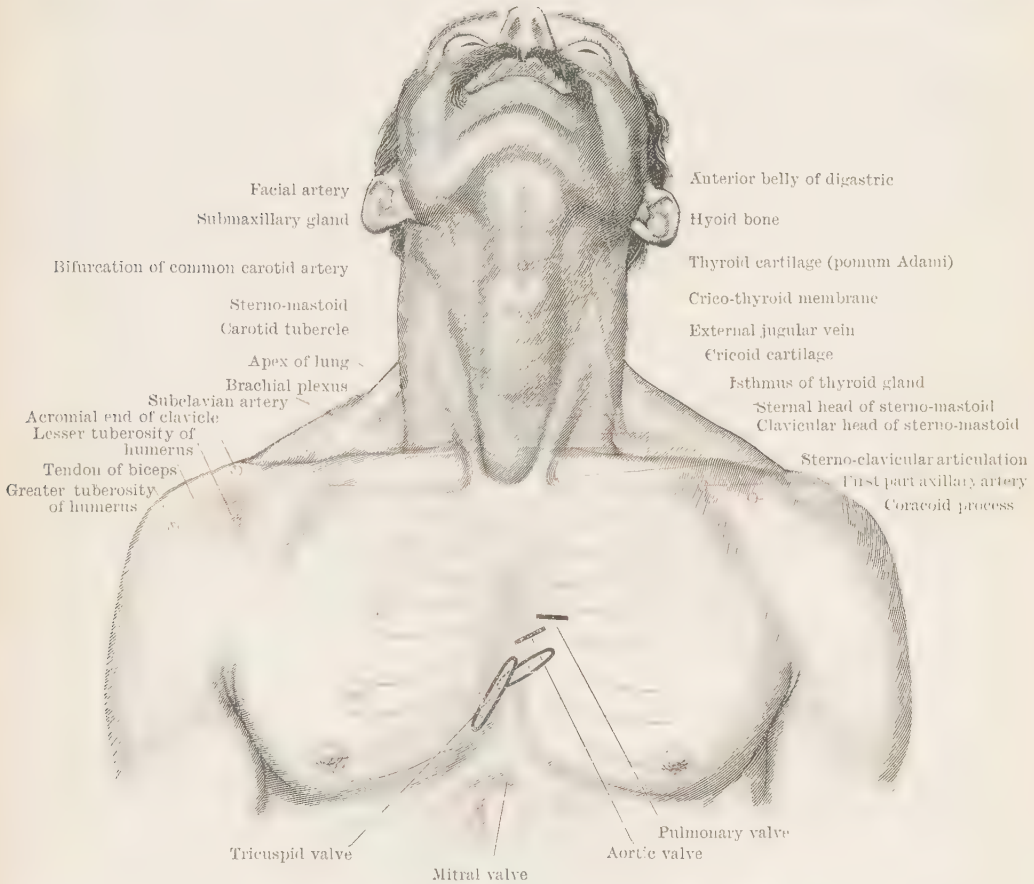

Fig. 898.—Anterior Aspect of Neck and Shoulders.

part of the anterior jugular veins, along with their transverse communicating branch, a little fat, and one or two lymphatic glands.

The **vascular compartment**, triangular in section, is bounded *anteriorly* by the general fascial envelope, which splits at the omo-hyoid to enclose the depressors of the hyoid bone; *posteriorly* by the prevertebral fascia; *internally* by the visceral compartment; *externally* by the meeting of the prevertebral fascia and the posterior layer of the sterno-mastoid sheath. This compartment contains the carotid vessels, and the internal jugular vein, and the following nerves, viz.: the vagus, the first part of the hypoglossal, the descendens hypoglossi, and the upper part of the spinal accessory. The **carotid chain of lymphatic glands** lies in the cellular tissue which connects the various structures in the compartment; normally they may be readily separated from the sheath of the internal jugular vein, to which, however, they become adherent when inflamed. A glandular abscess in this com-

partment usually points upon the surface, adhesions being formed, first, between the gland and the fascia, and, subsequently, between the latter and the cutaneous structures. In diffuse suppurative cellulitis of this compartment the pus burrows towards the root of the neck, and may reach either the mediastinum or the axilla.

**Middle Line of the Neck.**—The body of the **hyoid bone** divides the middle line of the neck into **supra-** and **infra-hyoid portions**. Above the hyoid bone is the **submental triangle**, with its apex at the lower border of the symphysis menti and its sides formed by the anterior bellies of the digastrics. In the floor of the triangle are the anterior portions of the mylo-hyoid muscles, separated by the median raphe (Fig. 79). The most important structures in the triangle are the **submental lymphatic glands**, which can usually be felt a little above the body of the hyoid bone. They are a frequent seat of abscess secondary to impetigo of the lower lip and chin. About 1 in. below the hyoid bone is the **pomum Adami**, more prominent in the male than in the female. On either side of the pomum Adami are the alæ of the thyroid cartilage, while between the latter and the hyoid bone is the **thyro-hyoid membrane**. In the operation of *sub-hyoid pharyngotomy* the epiglottis and the superior opening of the larynx are reached by passing through the anterior wall of the pharynx at the level of the thyro-hyoid membrane. The structures divided from without inwards are: the integuments, the sterno-hyoid, omo-hyoid, and thyro-hyoid muscles, the middle portion of the thyro-hyoid membrane, along with a layer of fat between it and the lower part of the epiglottis, and, finally, the glosso-epiglottidean ligament and fold of mucous membrane. The incision

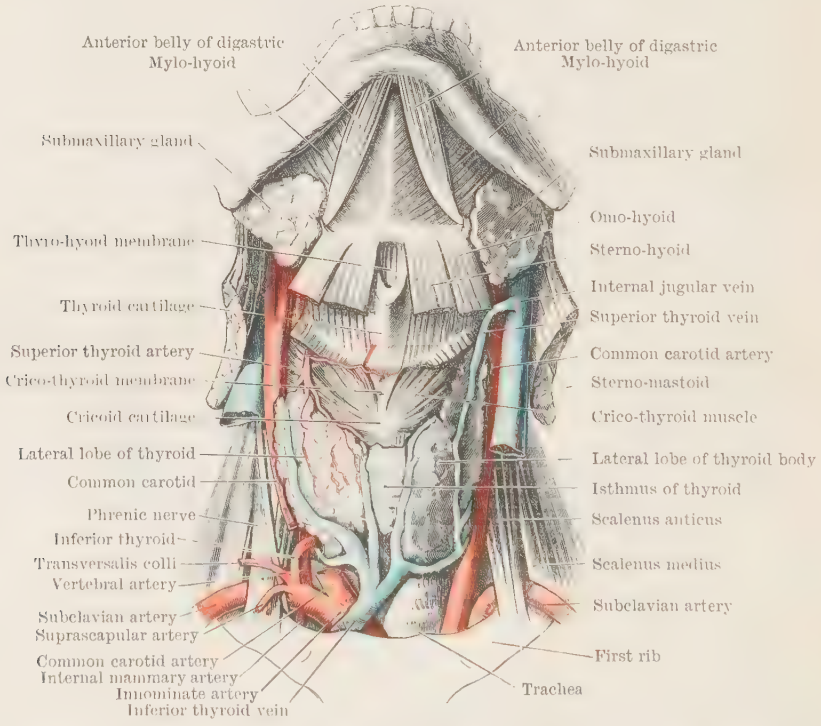

FIG. 899.—DISSECTION OF THE FRONT OF THE NECK. The lower portions of the sterno-mastoid muscles have been removed, and the lower part of the right common carotid artery cut away to show the deeper parts (from Cunningham).

must not be extended too far on either side of the mesial plane for fear of wounding the **superior laryngeal vessels** and **nerve** which pierce the thin lateral portions of the thyro-hyoid membrane.

The wound in suicidal *cut-throat* is generally at this level. The more important structures which are usually divided are: more or less of the left sterno-mastoid muscle, the superior thyroid vessels, the thyro-hyoid membrane, the base of the epiglottis, and, less frequently, the carotid vessels, the internal jugular vein, and the superior laryngeal nerve. When the wound

is above the hyoid bone, the lingual and facial vessels and the muscles of the tongue are the more important structures injured.

At the level of the middle of the anterior border of the thyroid cartilage is the **rima glottidis**. A little more than an inch below the pomum Adami is the anterior arch of the **cricoid cartilage**, which may be readily felt, and, when the neck is extended, often seen; it lies a little below a point midway between the lower margin of the chin and the upper border of the sternum. Above the cricoid is the **crico-thyroid membrane**; in the operation of laryngotomy only the middle portion of the membrane is divided, in order to avoid injury to the crico-thyroid muscles. The small crico-thyroid branch of the superior thyroid artery lies close to the lower border of the thyroid cartilage. Below the cricoid cartilage is the **trachea**, which recedes as it descends, so that it lies $1\frac{1}{2}$ in. from the surface at the level of the upper border of the sternum. The **isthmus** of the **thyroid gland** lies in front of the second, third, and fourth rings of the trachea (Fig. 872); not infrequently, however, it reaches up to the cricoid. Immediately in front of the trachea, below the isthmus of the thyroid, is the pretracheal fat, containing one or two **lymphatic glands** and the **inferior thyroid veins**, each represented by one or more branches which converge as they descend. The pretracheal lymphatic glands receive afferent vessels from the larynx and thyroid body, while their efferent vessels open into the inferior carotid glands. In the adult the **innominate artery** crosses the front of the trachea at the level of the upper border of the sternum; in the child, however, it not infrequently crosses half an inch higher, a relation which must be remembered in performing the operation of low tracheotomy.

In the operation of **high tracheotomy** the upper three rings of the trachea are divided. The incision, which should be mesial, divides the integuments, the tributaries of the anterior jugular veins, the general envelope of deep cervical fascia, and, after passing between the depressor muscles of the hyoid bone, the pretracheal fascia, which descends from the cricoid to enclose the isthmus of the thyroid gland. By dividing this fascia transversely below the cricoid, the isthmus may be pulled downwards and the upper rings of the trachea exposed. In some cases it is necessary either to divide the isthmus or to extend the incision upwards through the cricoid cartilage. In opening the trachea, the edge of the knife should be directed upwards so as to avoid injuring the vessels at the upper border of the isthmus. The anterior jugular veins are in danger of being wounded if the skin incision is not strictly mesial. In low tracheotomy the trachea below the isthmus is opened; it is a more troublesome operation on account of the depth of the trachea and the presence in front of it of the large inferior thyroid veins and of the transverse anterior jugular vein. In children the difficulty is increased by the higher position of the innominate artery and left innominate vein, by the presence of the thymus gland, and by the shortness of the neck.

**Triangles of the Neck.**—The lateral aspect of the neck may be divided into an **anterior** and a **posterior triangle** by the sterno-mastoid muscle; the former is further subdivided into *digastric, carotid,* and *muscular triangles* by the digastric and omo-hyoid muscles. The posterior triangle is subdivided into *occipital* and *clavicular portions* by the posterior belly of the omo-hyoid.

The **sterno-mastoid muscle** forms one of the most important superficial landmarks of the neck. The anterior border of the muscle, the more distinct of the two, may be felt along its whole extent. Between the prominent sternal origin and the broad ribbon-like clavicular origin is a slight triangular depression which overlies the lower part of the internal jugular vein.

**Digastric Triangle.**—This triangle is subdivided into an anterior or submaxillary portion and a posterior or parotid portion by the stylo-maxillary ligament. In the anterior portion is the **submaxillary gland**, which extends from the posterior half of the lower border of the mandible to the great cornu of the hyoid bone. The **facial vein** passes downwards and backwards superficial to the gland, while the **facial artery**, imbedded in its deep surface, arches upwards under cover of the angle of the jaw, where, according to Merkel, it approaches the tonsil, being separated from it, however, by the superior constrictor of the pharynx. The **lingual artery** may be ligatured in the digastric triangle, where it lies behind the

hyo-glossus a little above the great cornu of the hyoid bone; the superficial guides to the vessel are the lower border of the submaxillary gland, and the hypoglossal

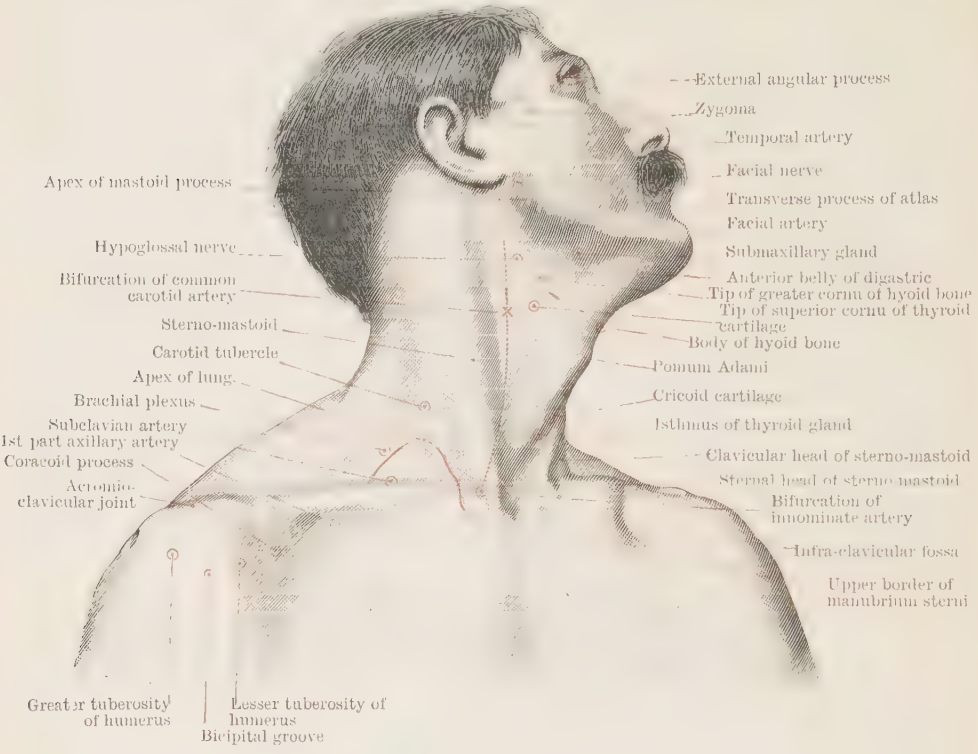

Fig. 900.—Lateral Aspect of Neck.

nerve and lingual vein, which lie upon the hyo-glossus, the latter being recognised by the vertical direction of its fibres. The *floor* of the digastric triangle is formed, from before backwards, by the mylo-hyoid, hyo-glossus, and superior constrictor of the pharynx. The **lymphatic glands** of this space receive their lymphatics from the face, lips, teeth and gums, tongue, and floor of the mouth. Suppurative cellulitis of the connective tissue of this space is called *angina Ludovici.*

**Carotid Triangle.**—The central landmark of this triangle is the **great cornu** of the **hyoid bone**, the tip of which, when the fascia is relaxed, may be readily felt immediately in front of the anterior border of the sterno-mastoid, at a point corresponding to the centre of a line drawn from the tip of the mastoid process to the pomum Adami. The deep cervical fascia holds the upper part of the sterno-mastoid forwards towards the angle of the jaw, so that, with the fascia undivided, the anterior border of the sterno-mastoid overlaps the internal jugular vein and the bifurcation of the common carotid artery.

The **course of the carotid vessels** is indicated upon the surface by a line extending from the upper end of the sterno-clavicular articulation to a point midway between the angle of the jaw and the tip of the mastoid process; a point upon this line, at the level of the upper border of the thyroid cartilage, overlies the **bifurcation of the common carotid**. The **anterior belly** of the **omo-hyoid** crosses the common carotid at the level of the cricoid cartilage. The pulsations of the carotid vessels may be felt in the hollow between the larynx and the anterior border of the sterno-mastoid. In the carotid triangle the **external carotid** lies internal and anterior to the internal carotid. The seat of election for *ligation of the external carotid* is between its superior thyroid and lingual branches, a finger's-breadth below the tip of the great cornu of the hyoid bone; the difficulty in the operation is due to the plexus of veins (formed by the common facial, lingual, and superior thyroid veins) which overlies the artery. The lingual and facial arteries frequently arise from a common trunk which must not be mistaken for the external carotid. The

**superior thyroid artery** arises opposite the upper cornu of the thyroid cartilage, which may be distinctly felt 1 in. below the tip of the great cornu of the hyoid bone. The vessel and its companion vein are common sources of hæmorrhage in cut-throat. The guide to the **lingual artery**, in the carotid triangle, is the tip of the great cornu of the hyoid bone, above which it forms an arch, crossed by the hypoglossal nerve. The vessel enters the digastric triangle by passing beneath the tendons of the stylo-hyoid and digastric muscles. When ligation of the artery is called for, it is, as a rule, preferable to secure it in the carotid rather than the digastric triangle.

From a surgical point of view the **internal jugular vein** is the most important structure in the anterior triangle. In the carotid division of the triangle it overlaps the carotid vessels, and its sheath lies close beneath the general envelope of deep cervical fascia. About the level of the hyoid bone it receives the large **common facial vein**, and it is the glands in the neighbourhood of those which overlie the junction of this vein with the internal jugular that are most frequently the seat of tubercular disease, because they receive efferent vessels from so many regions of the head and neck.

The **deep cervical chain of lymphatic glands** descends beneath the sterno-mastoid muscle from the subparotid glands above to the subclavian glands below. While the majority are related to the anterior and external aspects of the sheath of the internal jugular vein, there are others (receiving cutaneous lymphatics from the posterior part of the head and neck) which lie more posteriorly, in the fibro-fatty tissue which surrounds the upper part of the spinal accessory nerve and the branches of the cervical plexus.

The **hypoglossal nerve** curves forwards across the carotid vessels at the level of the lower border of the posterior belly of the digastric. The **vagus nerve** descends vertically behind and between the carotid vessels and the internal jugular vein; care must be taken not to include it when ligaturing the common carotid or internal jugular. Surgically, the **spinal accessory** is the most important nerve in the anterior triangle; it enters the substance of the sterno-mastoid muscle $1\frac{1}{2}$ in. below the tip of the mastoid process. A portion of the nerve is resected in the treatment of spasmodic wry-neck, and it is almost always exposed in the removal of the upper carotid group of deep cervical glands. The course of the nerve may be mapped out upon the surface by drawing a line from a point midway between the tip of the mastoid process and the angle of the jaw to the middle of the posterior border of the sterno-mastoid muscle, and thence across the posterior triangle to the anterior border of the trapezius, beneath which it passes at the level of the seventh cervical spine. The deeper guides to the nerve are the posterior belly of the digastric, the internal jugular vein, and the **transverse process of the atlas**, which is felt as a distinct bony landmark midway between the tip of the mastoid and the angle of the jaw. The **cervical sympathetic** lies in the posterior wall of the vascular compartment of the neck, and may be reached by an incision along the posterior border of the sterno-mastoid: the anterior surfaces of the roots of the transverse processes of the vertebræ are the deep guides to the nerve. The **cervical plexus**, which lies behind the upper half of the sterno-mastoid upon the levator anguli scapulæ and scalenus medius muscles, may be exposed through an incision along the posterior border of the upper half of the sterno-mastoid muscle. The **phrenic nerve**, the most important branch of the cervical plexus, arises one inch above the carotid tubercle and descends almost vertically upon the scalenus anticus; it is overlapped by the outer margin of the internal jugular vein.

The **muscular** or **lower carotid triangle** is an important triangular intermuscular space bounded by the anterior border of the sterno-mastoid, the anterior belly of the omo-hyoid and the sterno-hyoid. By making an incision along the anterior border of the left sterno-mastoid muscle, and passing through this triangle, the surgeon reaches, in order from before backwards, the internal jugular vein, the common carotid artery, the vagus, the thoracic duct (on the left side), the middle cervical ganglion of the sympathetic, the inferior thyroid artery, the vertebral vessels, the recurrent laryngeal nerve, and the œsophagus. The most important bony landmark in this triangle is the prominent anterior tubercle of the transverse

process of the sixth cervical vertebra. The common carotid artery may be compressed against this tubercle, which is therefore termed the "*carotid tubercle.*" As it is the most important guide to the vertebral artery, which enters the foramen in its transverse process, it is often referred to as the "*vertebral arterial tubercle.*"

In operations in this region, on the left side, it is important to avoid the **thoracic duct**, which extends upwards into the neck one inch vertically above the inner end of the clavicle, and, after arching outwards behind the common carotid, descends behind the lower inch of the internal jugular vein.

The **cervical portion** of the **œsophagus**, which begins at the level of the cricoid cartilage, descends behind, and a little to the left of, the trachea. To expose it, the surgeon, after passing through the above-mentioned muscular triangle, passes between the trachea and the carotid sheath; or it may be exposed through an incision in the middle line, the trachea, which is freely movable, being displaced to the right side. In opening the œsophagus care must be taken not to injure the **recurrent laryngeal nerve** which ascends in the groove between it and the trachea, and also that the loose submucous cellular interval must not be mistaken for the lumen of the tube. The recurrent laryngeal nerve must be avoided also in operations connected with the thyroid gland; it is most liable to be injured during the application of a ligature to the **inferior thyroid artery**, which arches inwards in front of the nerve to reach the posterior surface of the gland. Adjacent to the lateral aspects of the cervical portions of the trachea and œsophagus are a few small lymphatic glands which receive their efferent vessels from the larynx, trachea, œsophagus, and thyroid body. The efferent vessels from this chain join either the inferior carotid or subclavian glands.

The **Posterior Triangle.**—Imbedded in the deep cervical fascia at the posterior border of the sterno-mastoid muscle, is a chain of **lymphatic glands** which lies in close relation to the spinal accessory nerve and to the branches of the cervical plexus; these glands are a frequent source of abscess in pediculosis and impetigo of the scalp. The posterior belly of the omo-hyoid, which forms the upper boundary of the **supraclavicular division** of the posterior triangle, passes beneath the posterior border of the sterno-mastoid at a point about one inch above the clavicle. The **external jugular vein**, usually visible through the skin, runs in a line from the angle of the jaw to the middle of the clavicle; it is the vessel which is generally opened to relieve the right side of the heart in asphyxia. The lumen of the vein is kept patent where it pierces the fascia of the subclavian triangle; hence a wound of the vein in this situation is liable to be followed by the suction of air into the circulation during inspiration. The **third part** of the **subclavian artery** can be compressed against the first rib by pressing downwards and backwards immediately above the clavicle, a little behind the posterior border of the sterno-mastoid muscle. To map out the *course* of the subclavian artery in the neck, draw a line, convex upwards, from the upper border of the sterno-clavicular articulation to the middle of the clavicle, the highest part of the arch to reach from ½ to 1 in. above the bone. To *ligature the vessel* in the third part of its course, an angular incision is made along the middle of the upper border of the clavicle and the lower part of the posterior border of the sterno-mastoid muscle. The most important guides to the vessel are the posterior belly of the omo-hyoid, the outer border of the scalenus anticus, and the scalene tubercle of the first rib. The close relation of the vessel to the lowest trunk of the brachial plexus and to the cervical pleura must be kept in mind. In the rare instances in which a cervical rib is present the subclavian artery lies either in front of it, or arches above it, according to the degree of development of the rib. The **subclavian vein** lies below, and anterior to, the artery, altogether under cover of the clavicle.

Entering the posterior triangle from behind the outer border of the scalenus anticus are the trunks of the **brachial plexus**. They lie upon the scalenus medius, and can be felt through the skin immediately above and behind the third part of the subclavian artery. The anterior primary division of the fifth cervical nerve supplies the rhomboids, the abductors and external rotators of the arm, and the flexors and supinators of the forearm; that of the sixth the serratus, the adductors and internal rotators of the arm, and the extensors and pronators of the forearm;

that of the seventh the flexors and extensors of the wrist; that of the eighth the flexors and extensors of the fingers; that of the first dorsal all the small muscles of the hand. The carotid tubercle lies between the anterior primary divisions of the sixth and seventh cervical nerves. The fifth and sixth cervical nerves are those which suffer most when the plexus is injured by forcible depression of the shoulder while the head is bent to the opposite side, such as occurs, for instance, in the "Obstetrical Paralyses" of Duchenne.

To expose the trunks of the brachial plexus an incision is made from the junction of the middle and lower thirds of the posterior border of the sterno-mastoid downwards and outwards to the junction of the outer and middle thirds of the clavicle.

In the middle line of the neck posteriorly is the **nuchal furrow**, at the bottom of which are the cervical spines and the ligamentum nuchæ. At the upper part of the furrow, about two inches below the external occipital protuberance, is the large **spine of the axis**, which can be distinctly felt; a line drawn from it outwards and slightly upwards to the transverse process of the atlas corresponds to the position of the inferior oblique muscle and, therefore, to the lower margin of the **sub-occipital triangle**. The course of the deep part of the **great occipital nerve** may be mapped out by drawing a line from the centre of the above-mentioned line to a point one inch external to the external occipital protuberance. At the floor of the sub-occipital triangle is the posterior arch of the atlas upon which the **vertebral artery** lies.

## THE THORAX.

For the convenience of topographical description, clinicians, by the use of vertical and transverse lines, have arbitrarily divided the surface of the chest into certain definite regions or areas. The vertical lines are: the *mid-sternal*, the *lateral sternal*, the *para-sternal*, the *mammary* or *mid-clavicular*, the *anterior*, *mid*, and *posterior axillary*, and the *scapular*. The position of the mid and lateral sternal lines is sufficiently indicated by their names.

The **mammary**, better termed the **mid-clavicular**, is drawn vertically down from the centre of the clavicles, or, what comes to practically the same thing, from a point midway between the centre of the supra-clavicular notch and the tip of the acromion process. In the male this line usually lies $\frac{1}{2}$ to $\frac{3}{4}$ in. internal to the centre of the nipple, which is usually placed over the fourth interspace, or fifth rib, four inches from the middle line. In the child the nipple may be as high as the lower border of the third rib. In the female the position of the nipple is so variable that it is of no topographical value. In a well-proportioned subject, the mid-clavicular line, if prolonged downwards, will be found to be continuous with the vertical Poupart line, which crosses the costal margin at the tip of the ninth costal cartilage.

The **para-sternal line**, drawn midway between the lateral sternal and mid-clavicular, crosses the costal margin opposite the tip of the eighth costal cartilage.

The **anterior**, the **mid**, and the **posterior axillary lines** are respectively drawn downwards from the anterior fold, the apex, and the posterior fold of the axilla.

The **scapular line** is drawn perpendicularly through the inferior angle of the scapula.

Of the *two transverse lines*, the **upper**, which separates the **infra-clavicular** and **supra-sternal** regions from the **mammary** and **infra-sternal** regions, is drawn at the level of the third chondro-sternal articulation; the **lower**, which separates the **mammary** and **infra-mammary** regions, is drawn at the level of the sixth chondro-sternal articulation.

The lateral area of the chest is divided into an upper, or **axillary**, and a lower, or **infra-axillary** region, by a horizontal line drawn at the level of the sixth rib.

In muscular subjects there is a well-marked mesial furrow, the **sternal furrow**, between the sternal origins of the **pectoralis major muscles**. The inner part of the lower border of these muscles forms a curved prominence which, overlying the fifth rib, corresponds to the junction of the mammary and infra-mammary regions. Below this prominence is the infra-mammary region, which forms a somewhat flat

surface corresponding to the upper part of the rectus muscle. In the axillary and infra-axillary regions are the prominences caused by the digitations of origin of the **serratus magnus**, the first to appear below the pectoralis major being that which springs from the fifth rib.

The **upper border** of the **sternum** lies in the same horizontal plane as the lower border of the body of the second dorsal vertebra, the distance between the two being about two inches. The junction of the manubrium and the body of the sternum forms a slight prominence or angle, known as the *angulus Ludovici*, which, although not usually visible, may always be felt. The angulus lies in the same plane as the body of the fifth dorsal vertebra.

The **xiphi-sternal junction** corresponds to the disc between the ninth and tenth dorsal vertebræ. Immediately below the xiphi-sternal articulation is the **infra-sternal notch**, formed by the junction of the seventh costal cartilages with the sternum. Below the notch is the **epigastric fossa** or **triangle**, bounded laterally by the seventh costal cartilages. The apex of the triangle forms an angle which varies considerably according to the shape of the chest, the average being about 70°. Not infrequently the eighth costal cartilage articulates with the sternum.

**Fracture of the sternum** is rare, and generally occurs at or close to the junction of the manubrium and the body; it may occur either from direct violence, or indirectly along with fracture of the spine. Unlike that of the ribs, the periosteum covering the sternum is firmly adherent to the bone.

The **ribs**, which in well-nourished subjects cause no surface prominences, are readily visible in thin persons; in the obese they are very difficult to feel. In counting the ribs from the front, the *second* may always be identified by its relation to the angulus Ludovici. The *first rib* is to a large extent under cover of the clavicle. The lower border of the pectoralis major and the first visible digitation of the serratus magnus afford reliable guides to the *fifth rib*. The infra-sternal notch is the guide to the inner end of the *seventh costal cartilage*. The second and third costal cartilages are almost horizontal; below this the cartilages ascend with increasing obliquity, that of the sixth being the first to present a distinct angle. The inner end of the second intercostal space is the widest, while those of the fifth and sixth are very narrow.

The **costo-chondral junctions** may be indicated on the surface by a line drawn from the upper end of the para-sternal line to a point a finger's-breadth behind the angle of the tenth costal cartilage.

The **internal mammary artery** crosses behind the inner ends of the upper five intercostal spaces about half an inch from the edge of the sternum; as it descends it approaches a little nearer to the sternum. The vessel is accompanied by two veins which unite to form a single vein opposite the second interspace.

This artery is occasionally injured in punctured wounds of the chest. At the second or third intercostal space it is easily ligatured through a transverse incision, but at a lower level it is generally necessary to resect a portion of one of the costal cartilages.

## THE LUNGS.

The **apex** of the lung extends upwards into the root of the neck for a distance of one to two inches above the anterior extremity of the first rib, and is mapped out by a curved line drawn from the upper border of the sterno-clavicular articulation across the sterno-mastoid to the junction of the inner and middle thirds of the clavicle, the highest part of the curve reaching from $\frac{1}{2}$ to $1\frac{1}{2}$ in. above the clavicle. The apex of the right lung reaches half an inch higher than that of the left lung. Intimately related to the apex of the cervical pleura are the subclavian artery and the **inferior cervical ganglion** of the sympathetic.

Both the **cervical pleura** and the **subclavian artery** may be injured by one of the fragments in a fracture of the clavicle; the scaleni muscles, however, affording considerable protection to the former. In ligaturing the third part of the subclavian artery, care must be taken not to injure the cervical pleura.

To delineate the **anterior border** of the **right lung**, draw a line from the upper

border of the sterno-clavicular articulation to the centre of the manubrium sterni, and from thence vertically downwards, in or slightly to the left of the middle line, to the level of the sixth or seventh costal cartilage, or it may be even to the infra-sternal notch (Fig. 902).

The **anterior border** of the **left lung** is mapped out by a corresponding line as

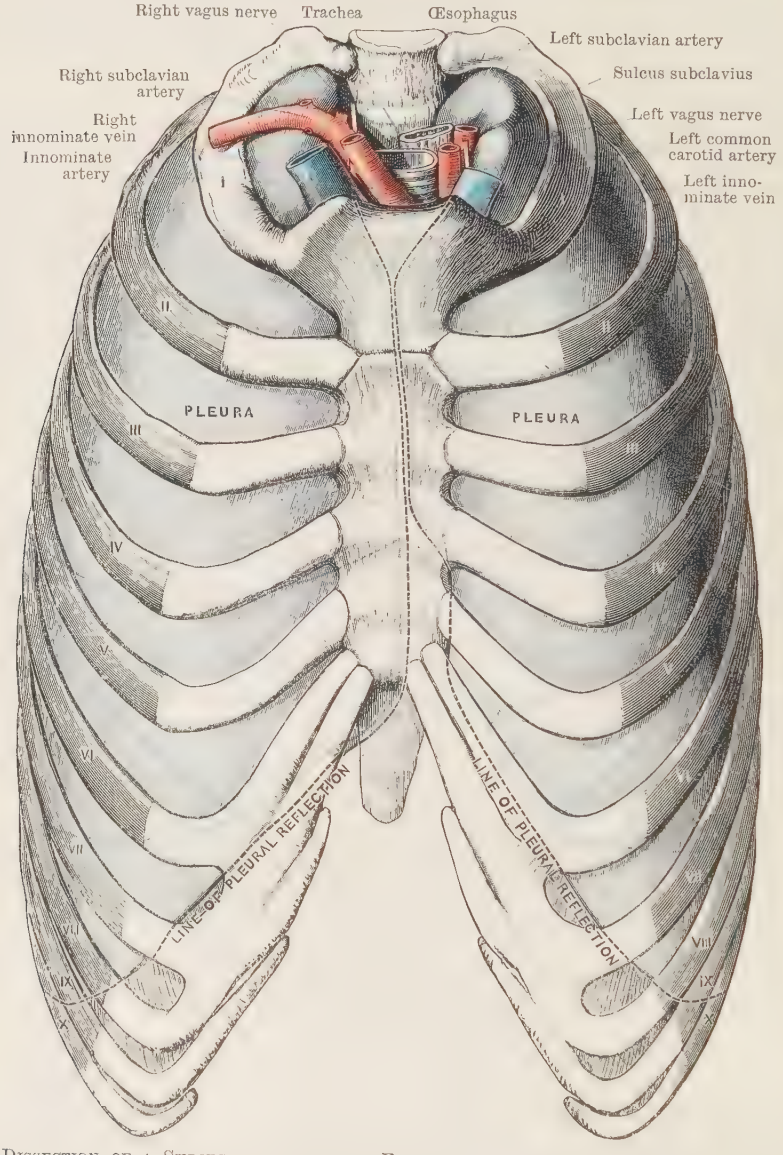

FIG. 902.—DISSECTION OF A SUBJECT HARDENED BY FORMALIN-INJECTION, to show the relations of the two pleural sacs as viewed from the front. The anterior and diaphragmatic lines of pleural reflection are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines (from Cunningham).

far as the fourth costal cartilage; thence it is directed outwards along the lower border of the fourth costal cartilage to the para-sternal line; it then passes downwards and slightly outwards across the fourth interspace, and curves inwards behind the fifth costal cartilage and fifth interspace to reach the upper border of the sixth costal cartilage in the para-sternal line. The lower part, therefore, of the anterior surface of the right ventricle is uncovered by lung and gives a completely dull note on percussion; this area is spoken of as the area of "*superficial or absolute cardiac dulness.*"

The level of the **lower border** of the lung is practically the same on both sides; it is mapped out by a line extending outwards from the lower extremity of the anterior border to the sixth costal cartilage in the mid-clavicular line, and thence in a slightly curved direction, with the convexity downwards, across the lateral aspect of the chest to the tenth dorsal spine. This line crosses the eighth rib in the mid-axillary line and the tenth rib in the scapular line (Figs. 904 and 905).

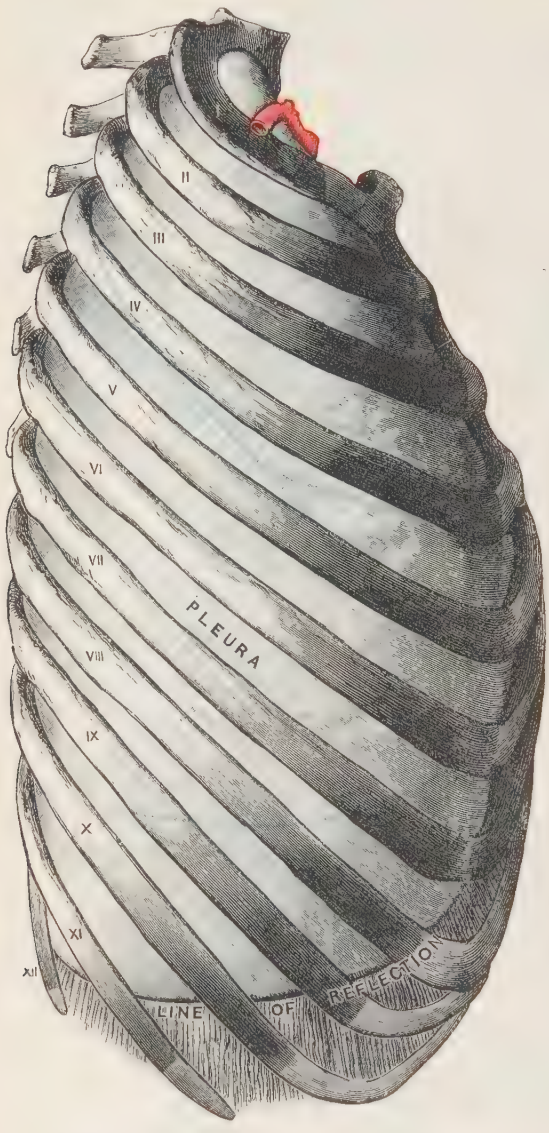

FIG. 904.—LATERAL VIEW OF THE RIGHT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION. The blue lines indicate the outline of the right lung, and also the position of its fissures (from Cunningham).

To indicate the position of the **oblique fissures** a line is drawn from the second dorsal spine across the interscapular region to the root of the spine of the scapula, and thence downwards and outwards across the infraspinous fossa, to end at the lower border of the lung opposite the sixth costal cartilage, a little internal to the mammary line. When the arm is raised above the level of the shoulder, and the hand placed on the back of the head, the inferior angle of the scapula is rotated upwards and forwards so that the vertebral border practically corresponds with the line of the oblique fissure.

The **transverse fissure** of the right lung is mapped out by drawing a line from the anterior border of the lung, at the level of the fourth costal cartilage, outwards and slightly upwards to join the middle of the oblique fissure.

**Pleura.**—The **line of reflection** of the **right pleura** from the back of the sternum may be said to correspond to the anterior border of the right lung.

On the **left side**, the pleural reflection corresponds to the anterior border of the left lung as far as the lower edge of the fourth chrondro-sternal junction, from which point it diverges slightly and descends behind the left border of the sternum to the sixth costal cartilage (Fig. 902). It is only occasionally that the inner extremities of the fifth and sixth interspaces are uncovered by pleura.

The **right costo-diaphragmatic reflection** (see Figs. 903 and 907) is indicated on the surface by a line drawn from the sixth or seventh chondro-sternal junction (sometimes the infra-sternal notch) downwards and outwards to a point two inches vertically above the angle of the tenth costal cartilage; from this point the line is carried with a slightly downward curve across the lateral aspect of the chest to the twelfth rib at the outer margin of the erector spinæ; thence it passes below the twelfth rib and reaches the vertebral column at the level of the upper border of the twelfth dorsal spine. The relation of the costo-diaphragmatic reflection to

the seventh, eighth, and ninth costal arches may be conveniently expressed by stating that it lies a little in front of the costo-chondral junction of the seventh, opposite that of the eighth, and a little behind that of the ninth.

The **left costo-diaphragmatic reflection** is indicated by a line drawn from a point opposite the sixth costal cartilage, a finger's-breadth from its junction with the sternum, to a point one and a half inches vertically above the angle of the tenth costal cartilage, and thence to the spine, as on the right side, but at a slightly lower level.

The costo-diaphragmatic reflection reaches its *lowest limit* a little behind the mid-axillary line two inches vertically above the tip of the eleventh costal cartilage, a level which may be readily indicated, according to Cunningham, by a point in the mid-axillary line intersected by a horizontal line drawn round the trunk at the level of the lowest part of the extremity of the first lumbar spine (Fig. 904). The same author localises the level of the diaphragmatic pleural reflection in the mammary line at the point where this line is intersected by another horizontal line at the level of the spine of the last dorsal vertebra.

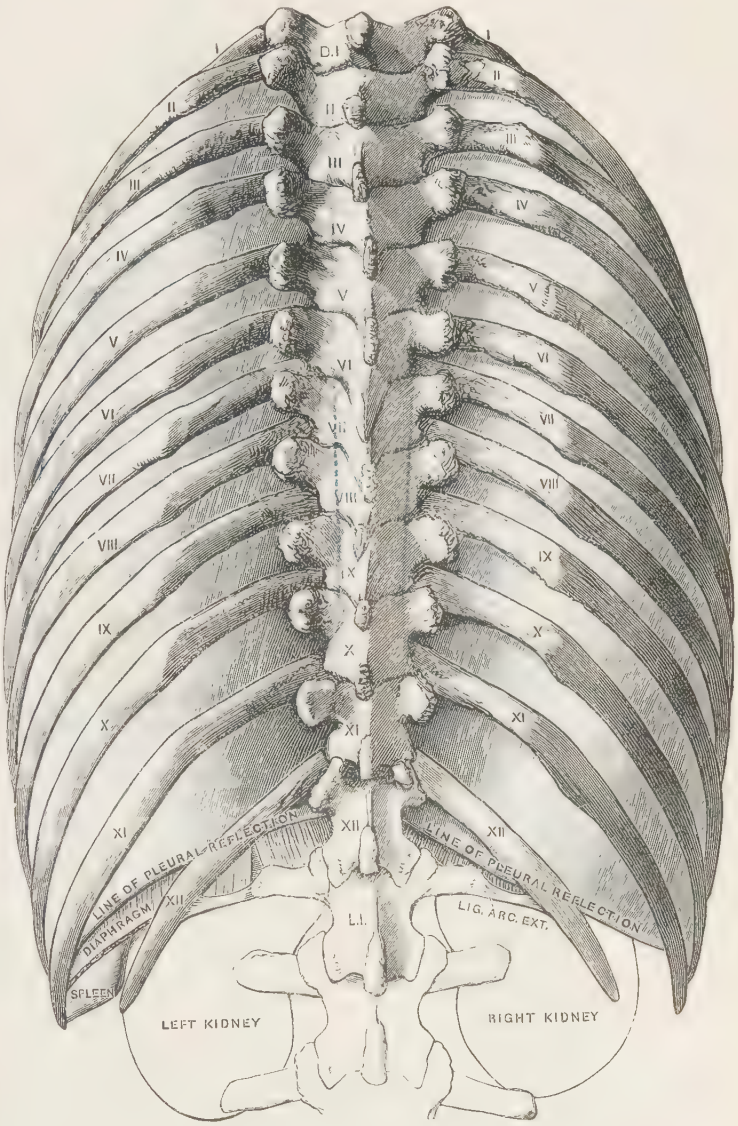

FIG. 905.—DISSECTION OF THE PLEURAL SACS FROM BEHIND.
The blue lines indicate the outlines and the fissures of the lungs (from Cunningham).

The **relations** of the **pleura** to the **twelfth rib** are of importance to the surgeon, especially in connexion with operations on the kidney (Figs. 905 and 906). When this rib is not abnormally short, the pleural reflection crosses it opposite the outer border of the erector spinæ muscle, hence an incision may be carried deeply as far as the apex of the angle formed by the twelfth rib and the outer border of the erector spinæ without entering the pleura. When, however, the twelfth rib does not reach the outer border of the erector spinæ, an incision carried upwards into the apex of the angle between this muscle and the eleventh rib is certain to wound the pleura (Melsome). It is important, therefore, to count the ribs from above downwards, in order not to mistake the eleventh for the twelfth, when the latter is rudimentary.

Internal to the outer edge of the erector spinæ the pleural reflection lies below the level of the twelfth rib, and not infrequently descends as far as the transverse process of the first lumbar vertebra.

On the *right side* the **posterior mediastinal pleura**, as it passes from the posterior aspect of the pericardium backwards to the front of the vertebral column sweeps over the

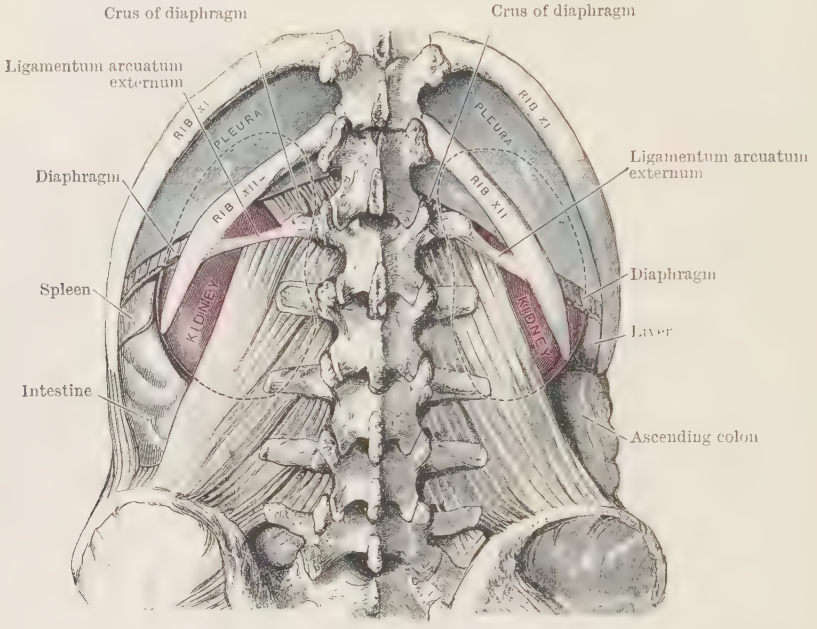

FIG. 906.—DISSECTION FROM BEHIND TO SHOW THE RELATION OF THE TWO PLEURAL SACS TO THE KIDNEYS. Outline of upper portions of kidneys indicated by dotted lines (from Cunningham).

right side of the œsophagus; hence malignant ulcers of the œsophagus are more likely to invade the right pleura than the left. On the *left side* the posterior mediastinal pleura passes from the lateral aspect of the bodies of the vertebræ on to the left side of the aorta. Hence, to evacuate pus from the posterior mediastinum, there is less risk of opening the pleura if the space be entered from the left side of the vertebral column.

The seat of election for *tapping the pleura* (*paracentesis pleuræ*) is the sixth or seventh costal interspace a little in front of the posterior axillary fold. To allow of the introduction of a tube to drain away the pus from the pleural cavity in empyema, a portion of one of the ribs (sixth to ninth) is resected. The intercostal vessels and nerves, which lie in the groove at the lower border of the rib, are avoided by removing the portion of bone subperiosteally. If the chest is opened in the scapular line care must be taken not to resect either the seventh or the eighth ribs, which are exposed when the arm is elevated, but overlapped by the angle of the scapula when the arm is lowered.

Anteriorly, the **bifurcation** of the **trachea** lies at or a little below the *angulus Ludovici*, while posteriorly it lies a little below the level of the root of the spine of the scapula, opposite the fourth dorsal spine. The bifurcation takes place one vertebra higher in the infant than in the adult (Symington).

The septum between the right and left bronchi lies a little to the left of the middle of the trachea, and the right bronchus is wider and more nearly in a line with the trachea than the left bronchus, hence the greater tendency of foreign bodies to enter the former.

The **roots** of the **lungs** are situated opposite the fourth, fifth, and sixth dorsal spines, midway between them and the vertebral borders of the scapulæ.

The lower end of the trachea, the bronchi, the vagi, and the left recurrent laryngeal nerve, are all more or less surrounded by lymphatic glands, which, when enlarged, may exert injurious pressure upon them.

## THE HEART AND GREAT VESSELS.

Viewed from the front, the **outline** of the **precordial area**, like that of the pericardial sac, is roughly triangular, the base of the triangle being below and the apex above. The boundaries are delineated upon the surface as follows:—

The *right side* of the triangle, formed by the right auricle, is indicated by drawing a line slightly convex outwards from the upper end of the third to the sixth costal cartilage a finger's-breadth from the edge of the sternum; the curve attains its maximum opposite the fourth intercostal space, where it reaches one and a half inch from the middle line.

The *base* of the triangle, formed by the *margo acutus* of the right ventricle and to a very slight extent by the apical portion of the left ventricle, is almost horizontal, and corresponds to a line drawn from the lower extremity of the right side of the triangle to the apex of the left ventricle, which lies behind the fifth left intercostal space, three and a half inches from the middle line and half an inch internal to the mid-clavicular line. The base line crosses the xiphoid cartilage at its junction with the body of the sternum.

The *left side* of the triangle, formed by the *margo obtusus* of the left ventricle, is indicated by a slightly curved line extending from the apex of the heart upwards to the lower edge of the second interspace, a finger's-breadth from the sternum, the convexity of the curve being directed outwards and slightly upwards.

The truncated *apex* of the triangle, which lies behind the sternum at the level of the second intercostal space, corresponds to the highest part of the heart, namely, where the auricular appendices embrace the aorta and pulmonary artery.

The anterior part of the right **auriculo-ventricular groove** is mapped out by a line drawn from the middle line, opposite the lower border of the third right costal cartilage, downwards and outwards to the sixth right chondro-sternal junction; the line should be slightly convex upwards and to the right. The **right auricular appendix** lies at, or a little to the left of, the middle line, at the level of the second intercostal space and the upper border of the third costal cartilage. The **left auricular appendix** lies behind the second left intercostal space, close to the edge of the sternum.

The *inferior surface* of the heart (facies diaphragmatica) rests upon the diaphragmatic or basal part of the pericardium. The true *posterior surface* of the heart is formed mainly by the **left auricle**, which is moulded posteriorly upon the œsophagus, the aorta, the bronchi, and the bronchial glands, the pericardium intervening. The left auricle extends behind the right auricle for a considerable distance to the right of the mesial plane.

In determining the position of the *cardiac orifices* and *their valves* it is to be remembered that they are all situated to the left of the right auriculo-ventricular groove, and that they lie in the following order from above downwards—viz. pulmonary, aortic, mitral, and tricuspid. When delineated on the surface they will be seen to lie within an ellipse whose long axis extends from the upper border of the third left to the sixth right chondro-sternal junction.

The **pulmonary orifice**, directed upwards and slightly backwards and to the left, lies opposite the upper border of the third left chondro-sternal junction; the **aortic orifice**, directed upwards, backwards, and to the right, lies further from the surface, behind the left half of the sternum, opposite the lower border of the third costal cartilage; the **mitral orifice** lies at a lower level behind the left half of the sternum, opposite the fourth rib; the orifice of the opening is directed downwards, forwards, and to the left. The **tricuspid orifice**, situated nearer the anterior wall of the chest than the mitral, lies very obliquely behind the right half of the sternum at the level of the fourth and fifth cartilages and intervening space.

Although the first and second **sounds of the heart** are heard all over the cardiac area, the sounds produced by the individual valves are heard most distinctly, not directly over their anatomical situation, but over the area where the cavity in which the valve lies approaches nearest to the surface. Hence the mitral sound is best heard over the apex (mitral area), the tricuspid over the lower part of the body of the sternum (tricuspid area), the aortic over the second right costal cartilage (aortic area), and the pulmonary over the second left intercostal space (pulmonary area).

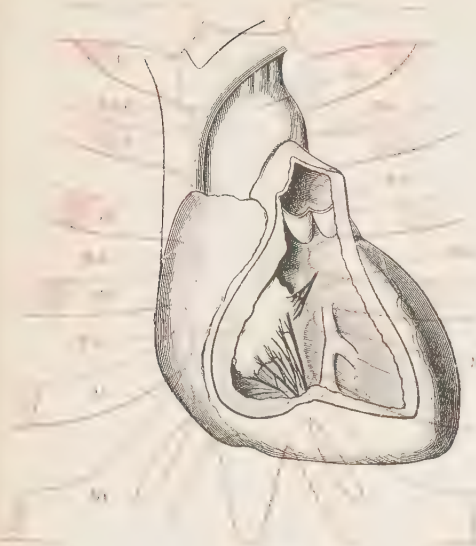

FIG. 908.

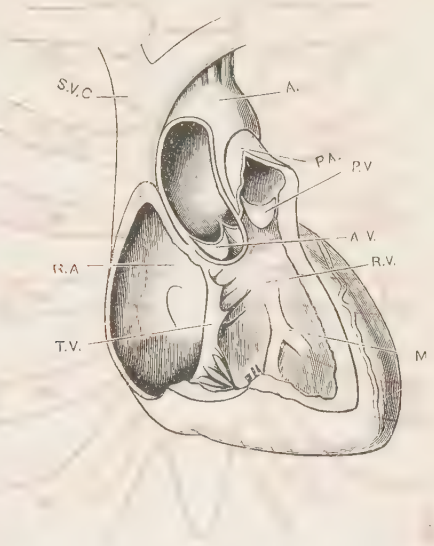

FIG. 909.

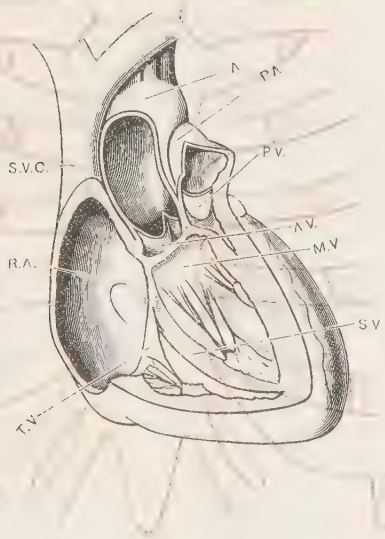

FIG. 910.

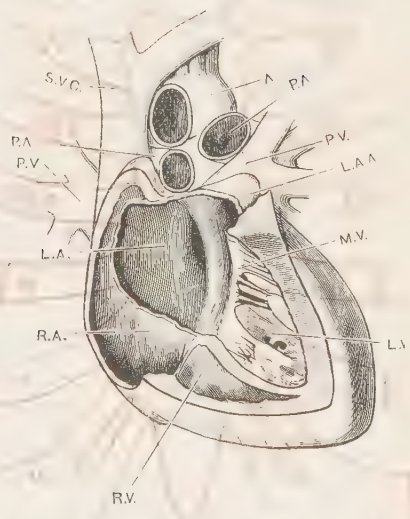

FIG. 911.

From photographs of a formalin-hardened subject, with the heart dissected *in situ*, to show the relations of its cavities and valves to the anterior wall of the thorax.

In Fig. 908 the anterior wall of the right ventricle has been removed and the pulmonary artery opened.

In Fig. 909 the anterior walls of the ascending aorta and of the right auricle have been removed; also the anterior cusp of the tricuspid valve.

In Fig. 910 the greater part of interventricular septum has been removed, exposing anterior cusp of mitral valve.

In Fig. 911 the ascending aorta, anterior cusp of mitral valve, trunk of pulmonary artery, and interauricular septum have been removed; the cavities of left auricle and left ventricle are exposed, also the left auricular appendix and posterior cusp of mitral valve.

In **tapping the pericardium** (paracentesis pericardii) the pleura will be avoided by making the puncture through the fifth or sixth left intercostal space as close as possible to the edge of the sternum. When, however, the pericardial sac is distended with fluid, the pleura is pushed outwards, and will therefore escape injury if the puncture be made at a safe distance external to the internal mammary vessels, viz. one inch external to the left border of the sternum.

To establish free drainage in suppurative pericarditis, the sixth left costal cartilage must be resected and the internal mammary vessels ligatured; the triangularis sterni and the pleural reflection are then pushed aside and the pericardium exposed and incised.

The **ascending aorta** lies behind the sternum, opposite the second and third ribs, and, unless dilated, does not project beyond its right border. The upper border of the **aortic arch** lies at or a little above the centre of the manubrium sterni; in the child the vessel may reach as high as the upper border of the manubrium.

The **innominate** and **left common carotid arteries** diverge from either side of the mesial plane between the upper part of the manubrium sterni and the front of the trachea. A pin pushed directly backwards immediately above the middle of the supra-sternal notch will strike the inner border of the innominate artery a little below its bifurcation.

The **pulmonary artery** lies behind the left border of the sternum opposite the second interspace and the second costal cartilage.

The **left innominate vein** lies behind the upper part of the manubrium sterni, the **right** behind the inner end of the right clavicle. The **superior vena cava** lies immediately to the right of the margin of the sternum, opposite the first and second interspaces and the intervening second rib; its opening into the right auricle, behind the third chondro-sternal articulation, corresponds to the centre of the root of the right lung.

**Œsophagus.**—The average length of the œsophagus in the adult is 10 in. (25 cm.); the distance from the incisor teeth to its commencement is 6 in.; to the point or level where it is crossed by the left bronchus, 9 in.; to the œsophageal opening of the diaphragm, 14 to 15 in.; to the cardiac orifice of the stomach, 16 in. These measurements, which are of great importance in diagnosing the seat of œsophageal obstructions, should be marked off from below upwards upon all œsophageal bougies and probangs. Posteriorly, the œsophagus extends from the level of the sixth cervical spine to that of the tenth dorsal, a little to the left of which is the situation at which the stethoscope is placed in order to hear the sound produced by the passage of fluid into the stomach.

Clinically it is important to bear in mind the relation of the œsophagus to the trachea and left bronchus, to the left recurrent laryngeal nerve, to the bronchial and posterior mediastinal glands, to the descending thoracic aorta, and to the right posterior mediastinal pleura. Ulcers of the œsophagus are liable to open into either the trachea, the left bronchus, or the right pleura.

The *veins* of the lower end of the œsophagus open partly into the systemic veins and partly into the portal system; like those at the lower end of the rectum they are liable to become varicose in conditions which give rise to chronic interference with the portal circulation.

The *lymphatics* of the upper part of the œsophagus open into the lower carotid glands, the remainder into the posterior mediastinal glands.

The œsophagus is very distensible in the transverse but not in the antero-posterior direction, hence the most useful forceps for removing foreign bodies from the œsophagus are those which open laterally.

## THE ABDOMEN.

### THE ANTERIOR ABDOMINAL WALL.

The configuration of the abdomen varies with the age, sex, obesity, and muscular development of the individual. In the child it is wider above than below, while the converse is the case in the adult female. It is most prominent in the region of the **umbilicus**, which is situated, normally, below the mid-point between the infra-sternal notch and the symphysis pubis, usually a little below the level of the highest part of the iliac crest, and opposite the middle of the body of the fourth lumbar vertebra. In the obese, and especially when the abdominal muscles have lost their tone, the umbilical region becomes prominent and more or less pendulous, so that the umbilicus may come to lie considerably below the normal level. In the child

it is relatively lower than in the adult, in consequence of the undeveloped state of the pelvis.

In spare subjects the lower end of the body of the sternum, the xiphoid cartilage, and the costal margin, can readily be traced. The slight depression or notch formed by the seventh costal cartilages and the lower border of the body of the sternum is termed the **infrasternal notch**. Below the notch, and bounded on either side by the seventh, eighth, and ninth costal cartilages, is the **infracostal angle**, which varies considerably according to the shape of the chest; it is relatively wider in the child than in the adult. The lower border of the curve of the **tenth costal cartilage** is easily recognisable, and has been selected by Cunningham as the level of the plane of separation (**infracostal plane**) between the upper and middle abdominal zones.

The anterior abdominal wall is limited below by the fold of the groin and the crest of the pubes. In a spare muscular subject the recti, the furrows corresponding to the **lineæ transversæ**, and the supra-umbilical portion of the **linea alba**, can be readily made out. When the outline of the rectus is not visible the outer border may be indicated by a line drawn from the tip of the ninth costal cartilage to the mid-point of a line joining the umbilicus and the anterior superior iliac spine, and from thence to the pubic spine. In the angle between the outer border of the rectus and the ninth costal cartilage, on the right side, is a slight triangular depression which overlies the fundus of the **gall-bladder**. Between the lower part of the outer border of the rectus and the prominence above the anterior part of the iliac crest, caused by the lower muscular fibres of the external oblique, is another slight triangular depression, which corresponds to the lower and narrow part of the aponeurosis of the external oblique muscle.

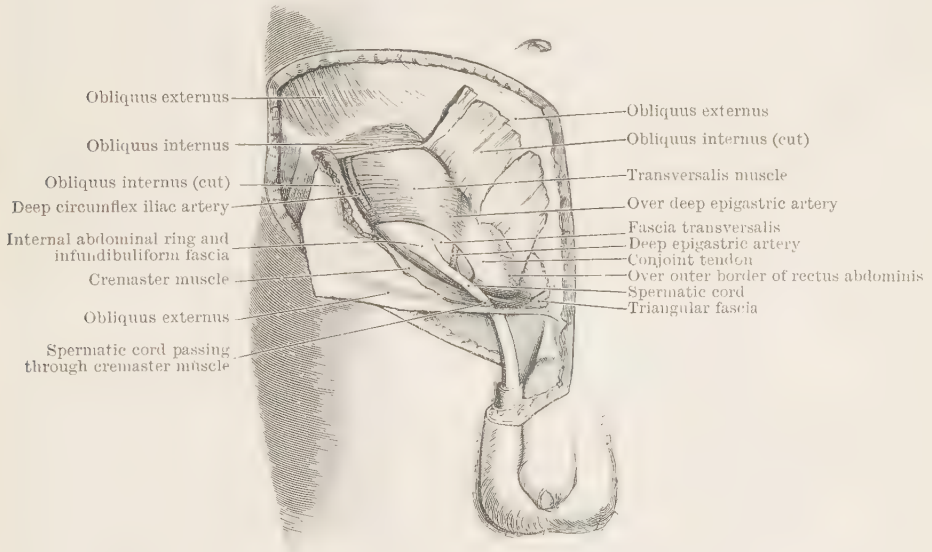

FIG. 912.—THE GROIN. The structures seen on reflexion of part of the obliquus internus (A. M. Paterson).

Close above, and almost parallel to, the inner half of Poupart's ligament is the **inguinal canal**, traversed by the **spermatic cord** (Fig. 912); the latter can be felt to emerge at the external abdominal ring immediately above the pubic spine. The **external** and **internal abdominal rings** have been fully described elsewhere; the former is triangular in shape, with its apex directed upwards and outwards, and its base immediately above the pubic crest. By invaginating the skin of the scrotum the little finger may readily be passed through the ring into the canal. It is to be noted that the neck of an *inguinal hernia* lies above the pubic spine, whereas the neck of a *femoral hernia* emerges below the inner end of Poupart's ligament, external to the pubic spine. The **internal abdominal ring**, an opening in the fascia transversalis, lies half an inch above a point a little internal to the

middle of Poupart's ligament. The **deep epigastric artery** may be mapped out by drawing a line from a point midway between the anterior superior iliac spine and the symphysis pubis towards the umbilicus. The vessel, together with the inner third of Poupart's ligament and the lower part of the outer border of the rectus, bounds a triangle known as **Hesselbach's triangle.** As the deep epigastric artery passes upwards and inwards to disappear behind the conjoined tendon and the outer border of the rectus, it lies behind the spermatic cord immediately internal to, and below, the internal abdominal ring. The floor of Hesselbach's triangle is formed throughout by the fascia transversalis, superficial to which, over the inner half or so of the triangle, is the **conjoined tendon.** An **oblique inguinal hernia** leaves the abdomen at the internal abdominal ring and traverses the whole length of the inguinal canal; its coverings are therefore the same as those of the spermatic cord, and the neck of the sac lies external to the deep epigastric artery, hence this variety of hernia is also termed an *external inguinal hernia.* A **direct inguinal hernia,** on the other hand, instead of traversing the whole length of the inguinal canal, pushes before it that part of its posterior wall which is formed by the floor of Hesselbach's triangle. The neck of the sac, therefore, lies internal to the deep epigastric artery, and this variety of hernia may be termed an *internal inguinal hernia.* If a direct hernia makes its way through the inner part of Hesselbach's triangle, it derives a covering from the conjoined tendon as well as from the fascia transversalis; if through the outer part of the triangle, the outer edge of the conjoined tendon curves round the inner side of the neck of the sac. To relieve the constriction at the neck of the sac, in the case of an *oblique inguinal hernia,* the edge of the knife is directed upwards and outwards to avoid the deep epigastric artery, while in a *direct hernia* the artery is avoided by dividing the constriction in an upward and inward direction. In an *oblique inguinal hernia* the sac lies within the infundibuliform fascia (fascia propria of the hernia), whereas in a *direct hernia* the fascia propria is derived from the fascia transversalis of Hesselbach's triangle. The extra-peritoneal fat which covers the outer surface of the hernial sac is sometimes hypertrophied to such an extent as to amount to a fatty tumour.

In a large proportion of children at birth the **funicular process** of peritoneum, which connects the tunica vaginalis testis with the abdominal peritoneum, especially on the right side, is still patent. Should the bowel force its way along the patent process a **congenital inguinal hernia** arises. In the majority of the cases of congenital inguinal hernia it will be found that the tunica vaginalis testis has been shut off by closure of the lower part of the funicular process, only the upper part remaining patent and forming the sac of the hernia. In regard to the operation for the cure of inguinal hernia, it should be borne in mind that in the acquired form the *hernia produces the sac,* whereas in the congenital variety the *sac is the cause of the hernia*; it follows, therefore, that in the operation for *acquired* hernia the closure of the canal is as important as the removal or obliteration of the sac, while in a *congenital* hernia the most essential part of the operation is the closure of the neck of the sac, and as the muscular and fascial apparatus forming the walls of the canal are well developed, they should be interfered with as little as possible. A patent funicular process may persist during adult life without any bowel descending into it; on the other hand, years after birth, bowel may suddenly enter it. In practically all oblique inguinal herniæ, which develop suddenly in children as well as in adolescents and young adults, the *sac* is of congenital origin.

In the ordinary form of hydrocele the fluid is confined to the tunica vaginalis testis, but when the funicular portion of the processus vaginalis remains patent, the hydrocele may extend upwards into the inguinal canal, and may or may not communicate with the general peritoneal cavity. In the condition known as encysted hydrocele of the cord the patent funicular process is shut off both from the tunica vaginalis testis and from the peritoneal cavity

Parallel to and at the level of the outer half of Poupart's ligament is the **deep circumflex iliac artery.** In dividing the abdominal wall to reach the structures in the iliac fossæ, the incision should be made in the angle between this vessel and the

deep epigastric artery. To lessen the risk of ventral hernia the muscles should be split in the direction of their fibres—the aponeurosis of the external oblique from above downwards and inwards, the muscular fibres of the internal oblique and transversalis horizontally. An incision through the abdominal wall parallel to the outer border of the rectus has the great disadvantage of dividing the **abdominal terminations of the lower intercostal nerves**, which run parallel to a line extending from the tenth costal cartilage to the umbilicus.

The middle line is the site usually selected by the surgeon to open the abdomen. The points of surgical importance to be noted in connexion with the **linea alba** are: (1) that its blood supply is scanty; (2) that it is considerably wider above than below the umbilicus, where the two edges of the recti lie in close apposition; (3) that above the umbilicus the fascia transversalis and linea alba are adherent, so that the two form practically one membrane; (4) that the extra-peritoneal fat is more abundant beneath the linea alba than to either side of it; (5) that above the pubes the fascia transversalis recedes from the linea alba, leaving a triangular space occupied by fat which must not be mistaken for the extra-peritoneal fat.

The posterior layer of the rectal sheath ceases at the **fold of Douglas**, which is situated one-third of the distance from the umbilicus to the pubes. The fleshy fibres of the transversalis muscles extend inwards for a considerable distance behind the upper part of the recti.

## THE ABDOMINAL CAVITY.

To simplify the topography of the abdominal viscera the abdomen is arbitrarily divided into nine regions by two horizontal and two vertical planes. Of the two horizontal planes, the **upper (infracostal) plane** is at the level of the lowest part of the tenth costal cartilages; the **lower (intertubercular) plane** is at the level of the tubercular points of the iliac crests. The **two vertical planes** correspond upon the surface to a line drawn vertically upwards on either side from a point midway between the anterior superior iliac spine and the pubic symphysis. Superiorly, these vertical planes generally strike the tip of the ninth costal cartilages. The subdivisions of the **upper zone** are termed the *epigastric* and *right* and *left hypochondriac regions*, of the **middle zone** the *umbilical* and *right* and *left lumbar regions*, of the **lower zone** the *hypogastric* and *right* and *left iliac regions*. The epigastric, umbilical, and hypogastric regions may be further divided into right and left halves by the median plane. The **xiphisternal junction** is on a level with the disc between the ninth and tenth dorsal vertebræ. The **infracostal plane** passes through the upper part of the third lumbar vertebra; the **intertubercular plane** through the fifth lumbar vertebra, about one inch above the sacral promontory. The umbilicus is usually situated from one to two inches above the intertubercular line.

In the method of surface topography employed by Addison the plane of separation between the superior and middle abdominal zones is placed midway between the suprasternal notch and the upper border of the pubic symphysis. It will be found to lie at or near the mid-point between the xiphisternal junction and the umbilicus. Posteriorly, this plane strikes the lower border of the first lumbar vertebra, and it so constantly passes through the pylorus that it may with advantage be termed the **transpyloric plane**.

The **peritoneal cavity** may be regarded as a large and complicated lymph sac which is intimately related to the abdominal viscera, and more especially to the gastro-intestinal canal. Inflammatory infections of the peritoneum are therefore almost always secondary to lesions of the viscera. The peritoneal lymph sac is brought into direct communication with the subperitoneal lymphatics of the diaphragm through stomata which open upon the peritoneum covering the under surface of that muscle. The healthy peritoneum, in virtue of the vital action of its endothelial cells, is endowed with great absorptive properties, and, when irritated, has the power of throwing out an abundant exudation. The reflection of the peritoneum and its relations to the various organs have been elsewhere fully described (p. 1097).

From the surgical point of view the peritoneal cavity may be arbitrarily divided into **four great subdivisions**: viz. 1) that between the transverse mesocolon and the

diaphragm; (2) that between the transverse mesocolon and the mesentery of the small intestine; (3) that between the mesentery and the true pelvis; (4) that in the true pelvis. The **lesser sac** of the peritoneum may be looked upon as a diverticulum of the first-mentioned subdivision.

The attachment of the **transverse mesocolon** to the posterior abdominal wall is at the level of the second lumbar vertebra, and lies, therefore, a little above the infracostal plane. The attachment, which ascends slightly as it passes from right to left, crosses the right kidney, the second part of the duodenum, and the head of the pancreas, after which its attachment follows the anterior border of the pancreas. The *peritoneal subdivision above this attachment* is roofed in by the diaphragm, and includes the upper part of the greater sac, and, behind it, the larger portion of the lesser sac. The organs related to this area of the peritoneum are the liver, along with the bile ducts and gall-bladder, the stomach and part of the duodenum, the spleen, the pancreas, the upper part of the kidneys, and the suprarenal capsules. Suppuration connected with any of these organs is liable to spread upwards under the cupola of the diaphragm, producing what is known as *subphrenic abscess*. The routes followed to drain this region of the peritoneal cavity are either (1) through the anterior abdominal wall and the gastro-hepatic or gastro-colic omenta; (2) through the loins below the twelfth ribs; (3) through the chest wall, the lower part of the pleural cavity, and the diaphragm, steps having been previously taken to shut off the drainage-track from the pleural cavity. This subdivision of the peritoneal cavity may become shut off from the rest of the space by adhesion of the great omentum to the peritoneum of the anterior abdominal wall.

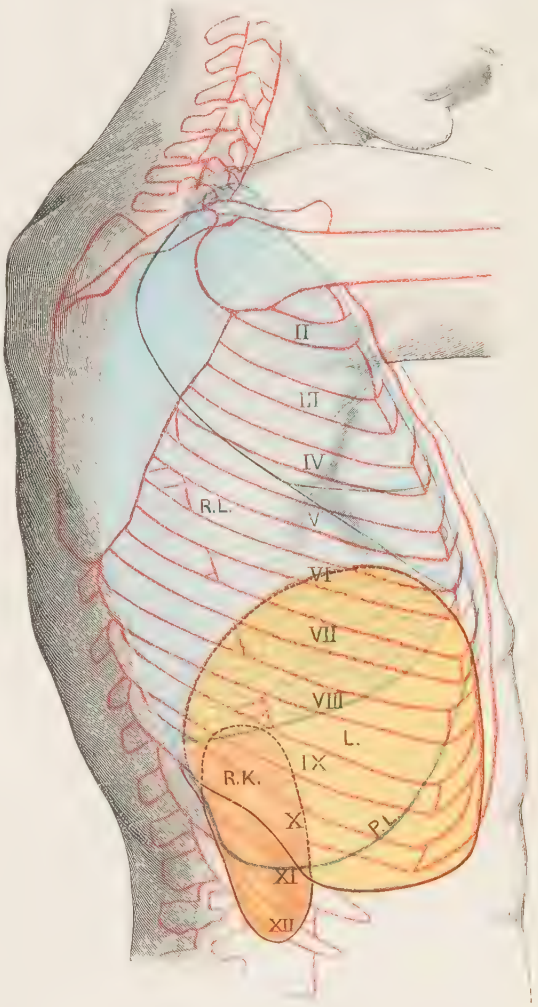

Fig. 914.—Lateral Aspect of Trunk, showing Surface Topography of Viscera.

R.L. Right lung. R.K. Right kidney.
L. Liver. P.L. Pleura.

The attachment of the **mesentery** of the **small intestine** extends from the left side of the second lumbar vertebra downwards to the right iliac fossa (Fig. 744, p. 1051). The attachment may be mapped out on the surface by drawing a line from a point on the transpyloric line, one inch to the left of the middle line, to the mid-point of a line drawn horizontally between the right anterior superior iliac spine and the middle line. The *subdivision between the transverse mesocolon and the mesentery proper* is related more particularly to the small intestine, the cæcum and vermiform appendix, the ascending colon, the right ureter, and part of the right kidney. Suppuration in connexion with the organs in this area involves more especially the right lumbar region, and may extend upwards along the colon into the subdiaphragmatic region, or downwards into the true pelvis. To drain this region a tube is introduced into the right lumbar region either through the anterior abdominal wall or through the right loin.

The *peritoneal subdivision below the mesentery* corresponds to the left umbilical, left lumbar, and left iliac regions, and is related to the duodeno-jejunal junction, the greater part of the small intestine, part of the transverse colon, the splenic flexure, the descending colon, the iliac colon, the lower part of the left kidney, the left ureter, the lower part of the abdominal aorta, and the common iliac arteries. Suppuration in this division is very liable to extend downwards into the pelvis. Drainage may be established by the introduction of a tube either through the anterior abdominal wall or through the left lumbar region. If suppuration occur in the pelvis, drainage may be carried out through the anterior abdominal wall or, in the case of the female, through the vagina.

**Liver.**—The *lower border of the liver,* as it crosses the costal angle, can readily be determined by palpation and light percussion: it passes from the eighth left to the tip of the tenth right costal cartilage, and crosses the mesial plane at the level of the transpyloric line. In the *mid-axillary line* it reaches down to a point a little below the lowest part of the tenth right costal cartilage. Above the left costal margin the lower border passes upwards and to the left to join the left extremity of the liver at the fifth interspace in the mammary line. The *highest part of the liver,* which corresponds also to the highest part of the right arch of the diaphragm, reaches, during expiration, to the level of the fourth intercostal space in the mammary line. To the right of the mesial plane the upper border of the liver is too far removed from the anterior wall of the chest, and overlapped by too thick a layer of lung substance, to be accurately determined by percussion. *Behind the sternum* the upper border reaches to the level of the sixth chondro-sternal junctions. To the left of the mesial plane the upper limit of the liver cannot be determined by percussion as it merges into the cardiac dulness. The **falciform ligament** of the liver lies, as a rule, a little to the right of the mesial plane.

The anterior surface of the liver may be reached through a mesial incision extending downwards from the ensiform cartilage, or by an oblique incision a finger's breadth below and parallel to the right costal margin. To obtain free access to the upper surface the eighth and ninth costal cartilages must be resected; the seventh cartilage should, if possible, be avoided, otherwise the pleural, and even the pericardial cavity, may be opened. Division of the round and falciform ligaments allows of greater downward displacement of the liver. To reach the centre of the lateral surface of the right lobe portions of the seventh and eighth ribs should be resected in the mid-axillary line, and both the pleural and peritoneal cavities must be traversed.

The relation of the fundus of the *gall-bladder* to the surface is subject to considerable variation. Normally it is situated opposite the angle between the ninth costal cartilage and the outer border of the rectus; exceptionally it is pendulous and suspended from the liver by a more or less distinct mesentery; or it may be elongated and drawn downwards by adhesion to the duodenum or colon. When displaced downwards it is liable to be mistaken for a floating kidney, but may be distinguished from it by the fact that although it may be pushed backwards into the lumbar region it returns at once to its habitual position immediately behind the anterior abdominal wall as soon as it ceases to be manipulated. The *cystic duct,* which is about an inch and a half in length, is sharply bent upon itself close to its origin at the neck of the gall-bladder. It joins the hepatic duct at a very acute angle. The passage of a probe along the *normal* duct is rendered difficult by the marked flexure at its commencement, as well as by the folded condition of its mucous membrane; hence also the frequency with which calculi become impacted at the neck of the gall-bladder. In excising the gall-bladder, it is an advantage to ligature and divide the cystic artery and duct before proceeding to detach the organ from the under surface of the liver. The *common bile-duct,* about three and a half inches in length, lies, in its *upper third,* close to the right free border of the gastro-hepatic omentum. When cutting into this, the most accessible part of the duct, it should be drawn forward by the finger introduced behind it, through the foramen of Winslow; the portal vein, which must be avoided, lies behind and a little to the left of the duct. The *middle third* of the common duct lies a little to the right of the commencement of the gastro-hepatic artery behind the first part of the duodenum

about a finger's breadth from the pylorus. The *lower third* of the duct which passes downwards and to the right, is intimately related to the pancreas, and is usually so embedded in the posterior aspect of its head that it cannot be freed by blunt dissection. Close to its termination the common duct is joined by the pancreatic duct, the two opening separately, but close together, at the bottom of a diverticulum (ampulla of Varter), which pierces the wall of the duodenum obliquely, and opens at the summit of a small papilla situated at the lower part of the inner wall of the descending portion of the duodenum, about four inches from the pylorus. When a calculus becomes impacted in the ampulla, there is retention of the pancreatic as well as of the biliary secretion. Not infrequently there is an accessory pancreatic duct (duct of Santorini) which opens into the duodenum at a higher level than the main duct, which it joins by its other extremity. A calculus in the ampulla may be reached either by opening the duodenum from the front (trans-duodenal route), or by freeing the duodenum and gaining access to the duodenum from behind (retro-duodenal route). In the latter instance an incision is made external to the outer border of the second part of the duodenum, through that portion of the peritoneum which ascends from the upper layer of the transverse mesocolon over the anterior surface of the hepatic area of the kidney. By blunt dissection directed inwards behind the duodenum, this organ, along with the adjacent part of the head of the pancreas, can be separated from the kidney and vena cava and folded over towards the left, like a door on its hinges. In freeing the bile-duct from the posterior aspect of the head of the pancreas a vein of considerable size will be encountered; this vein, which returns the blood from the pancreatic-duodenal system of arteries, lies close to the bile-duct as it ascends behind the head of the pancreas to open into the commencement of the vena porta. Of the lymphatic glands related to the bile passages it is to be remembered that one lies at the neck of the gall-bladder, another at the junction of the cystic and hepatic ducts, while a third lies close to the termination of the common duct. When these glands are enlarged and indurated, care must be taken not to mistake them for impacted gall-stones.

**Stomach.**—The stomach lies almost entirely within the left half of the epigastric and the left hypochondriac regions. The **cardiac orifice**, which lies 1 in. below and to the left of the œsophageal opening in the diaphragm, is about 4 in. from the surface, and corresponds, on the anterior surface of the body, to a point over the seventh left costal cartilage 1 in. from the sternum. The **pylorus**, which is generally partly overlapped by the lower margin of the liver, lies, as a rule, about one inch to the right of the mesial plane; when the stomach is *empty* it generally lies in the mesial plane, when *distended* it may reach two, or even three, inches to the right of the middle line. The pyloric portion of the stomach is practically bisected by a horizontal plane which passes through the abdomen at the level of a point midway between the suprasternal notch and pubic symphysis (Addison); it lies, therefore, three to four inches below the infrasternal notch, midway between it and the umbilicus, opposite the first lumbar vertebra. The highest part of the **fundus** of the **stomach** corresponds to the left vault of the diaphragm, and lies at the level of the fifth rib in the mammary line, a little above and behind the apex of the heart. The **greater curvature** crosses behind the left costal margin opposite the tip of the ninth costal cartilage, that is to say, where the transpyloric line intersects the vertical Poupart line. The lowest part of the great curvature, situated generally in the mesial plane, extends down to, or a little above, the infracostal plane, about two inches above the umbilicus. The **lesser curvature** and the adjacent part of the anterior wall of the stomach are overlapped by the lower margin of the liver.

Overlying the stomach is an important surface area known to clinicians as the **semilunar space of Traube.** This space, which yields a deeply tympanitic note on percussion, is bounded above by the lower margin of the left lung; below, by the left costal margin; to the right, by the lower edge of the left lobe of the liver; behind and to the left, by the anterior border and anterior basal angle of the spleen. The line of the costo-diaphragmatic pleural reflection crosses the space about midway between its upper and lower limits. The tympanitic area of the space is

diminished superiorly by pleuritic effusion, towards the right by enlargement of the liver, and towards the left by enlargement of the spleen.

Perforation of an ulcer on the *anterior wall* of the stomach leads to extravasation into the greater sac of the peritoneum, while if the perforated ulcer be upon the *posterior wall*, extravasation takes place into the lesser sac. The close relation of the splenic artery and its branches to the posterior wall of the stomach explains the severe hæmorrhage which is sometimes caused by a posterior gastric ulcer. The surgeon may reach the posterior wall of the stomach through the gastro-colic omentum, or, after throwing upwards the great omentum and transverse colon, by traversing the transverse mesocolon; by the former route the posterior wall of the stomach is reached through the anterior wall of the lesser sac, in the latter case through its posterior wall.

**Duodenum.**—The **first part** of the duodenum, situated in the right half of the epigastrium, lies behind the eighth costal cartilage, immediately internal to the gall-bladder, and is overlapped by the quadrate lobe of the liver. If the finger be passed above this part of the duodenum and towards the left, behind the right free border of the lesser omentum, it will occupy the **foramen of Winslow**, which is just large enough to easily admit the finger. In resecting the pylorus, the surgeon should remember that the gastro-duodenal vessels lie behind the first part of the duodenum, about one inch to the right of the pylorus.

The **second part** of the duodenum descends in the right vertical Poupart plane, and is crossed about its middle, at the level of the infracostal plane, by the attachment of the transverse mesocolon. It lies in front of the hilum and lower part of the inner border of the right kidney.

The *transverse portion* of the **third part** of the duodenum occupies the upper part of the umbilical region, and crosses the middle line about one inch above a line joining the highest part of the iliac crests; behind its commencement is the upper part of the right ureter.

The *ascending portion* of the **third part** of the duodenum crosses the infracostal plane, and ascends upon the left side of the vertebral column opposite the second and third lumbar vertebra.

The **duodeno-jejunal flexure**, which lies in the transpyloric plane one inch to the left of the mesial plane, is the landmark which the surgeon makes for when he wishes to identify the commencement of the jejunum (Fig. 746, p. 1054). To find the flexure the omentum and transverse colon should be thrown upwards and the finger passed along the lower layer of the transverse mesocolon to the left side of the vertebral column. The flexure lies in the angle or recess formed by the left side of the second lumbar vertebra and the under surface of the body of the pancreas. With the finger in this recess the commencement of the jejunum may be hooked forward a little to the left of the superior mesenteric vessels at the root of the mesentery. In connexion with the duodeno-jejunal junction is the **duodeno-jejunal fossa** (inferior duodenal fossa of Jonnesco), formed by a fold of peritoneum which stretches from the left side of the fourth or ascending part of the duodenum upwards to become attached to the peritoneum of the posterior abdominal wall close to the inner border of the left kidney. The free edge of the fold and the mouth of the fossa look upwards. This is one of the situations at which an internal hernia sometimes develops, the sac, as it enlarges, extending further and further into the extra-peritoneal tissue on the posterior abdominal wall. Should strangulation occur, the lower edge of the orifice must be divided in a downward direction, in order to avoid the superior mesenteric vein which curves round the anterior and upper aspects of the orifice (Treves).

**Small Intestine.**—The coils of the small intestine dip downwards into the pelvis, overlap the ascending and descending portions of the colon, and extend upwards to the attachment of the transverse mesocolon. To the left of the mesentery they reach as far as the under surface of the pancreas and the splenic flexure of the colon; here they are overlapped by the lower part of the stomach, from which they are separated by the transverse mesocolon. The only certain means which the surgeon has of distinguishing the upper from the lower coils of small intestine is by their relation to the duodeno-jejunal flexure and the ileo-

cæcal junction. Occasionally the Peyer's patches can be seen from the peritoneal aspect and the ileum thereby identified. The *terminal portion of the ileum*, which is attached by the lower end of the mesentery to the upper part of the right lateral wall of the true pelvis, crosses over its brim, and ascends along the inner edge of the cæcum before opening into it. The terminal loop of the ileum may be hooked up by passing the finger along the inner side of the cæcum downwards over the inner border of the psoas and the external iliac vessels into the pelvis.

Meckel's diverticulum, which is due to persistent patency of the proximal portion of the vitelline duct, is usually situated from two to three feet above the ileo-cæcal valve; its average length is two inches. Springing from the antimesenteric border of the ileum, its termination is usually free, but it may be adherent either to the anterior abdominal wall, to the mesentery, or, more rarely, to one of the adjacent viscera. When its termination is fixed it may give rise to strangulation of the intestine.

**Large Intestine.**—The **cæcum**, which occupies the right iliac region, comes into contact with the anterior abdominal wall immediately above the outer third of

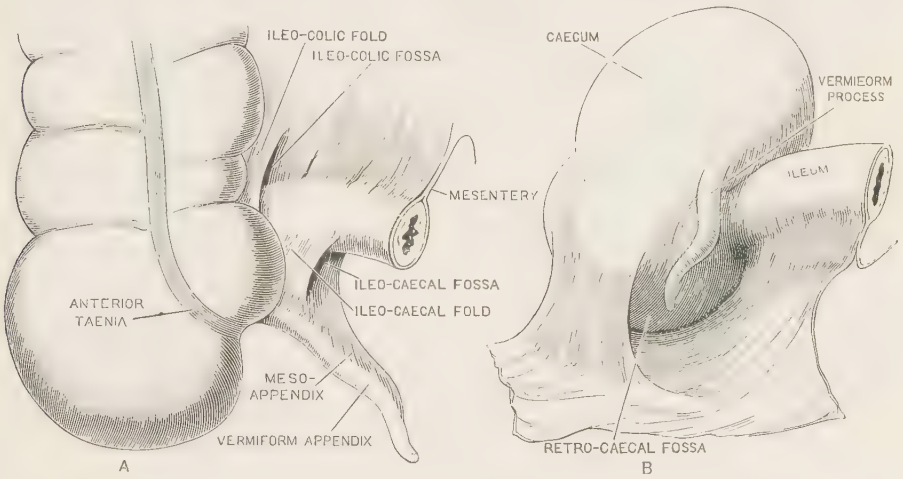

Fig. 915.—The Cæcal Folds and Fossæ.

In A, the cæcum is viewed from the front; the mesentery of the appendix is distinct, and is attached above to the under surface of the portion of the mesentery going to the end of the ileum. In B, the cæcum is turned upwards to show a retro-cæcal fossa, which lies behind it, and the beginning of the ascending colon (from Birmingham).

Poupart's ligament; laterally, it extends from the anterior superior iliac spine to the brim of the pelvis. When dilated, it extends considerably beyond these limits; when empty, it is generally more or less completely overlapped by small intestine. The **ileo-cæcal valve** lies at the junction of the intertubercular and Poupart planes (Fig. 913 V).

The orifice of the **appendix** opens upon the postero-internal aspect of the cæcum about an inch below the ileo-cæcal valve, a point which, according to M'Burney, may be located on the surface at the junction of the outer and middle thirds of a line drawn from the umbilicus to right anterior superior iliac spine. The appendix will generally be found to pass either upwards and inwards behind the lower end of the ileum, or downwards and inwards so as to overhang the external iliac vessels at the brim of the pelvis; less frequently it ascends in the pouch behind the commencement of the ascending colon. The *blood supply of the appendix* is derived from a single artery (a branch of the ileo-colic) which occupies the small mesentery of the appendix (Fig. 916); hence interference with the flow of blood along this vessel, either mechanically or from disease, predisposes to gangrene of the appendix. In opening the abdomen to remove the appendix it is usual either to split the three lateral abdominal muscles in the direction of their fibres ("gridiron" incision) or to pass through the sheath of the rectus, in which case the muscle itself is either pulled inwards or its fibres separated. When the gridiron incision is made

as long as possible, it is necessary to divide both the ascending branch of the deep circumflex iliac and the deep epigastric vessels, the former at the outer and the latter at the inner extremity of the incision. After dividing the peritoneum, the appendix is sought for by passing the finger behind the angle formed by the inner aspect of the cæcum and the lower end of the ileum. It may be necessary to bring the cæcum out of the wound, in order that the anterior longitudinal band of muscular fibres (tænia coli) may be traced downwards to the root of the appendix (Fig. 915, A).

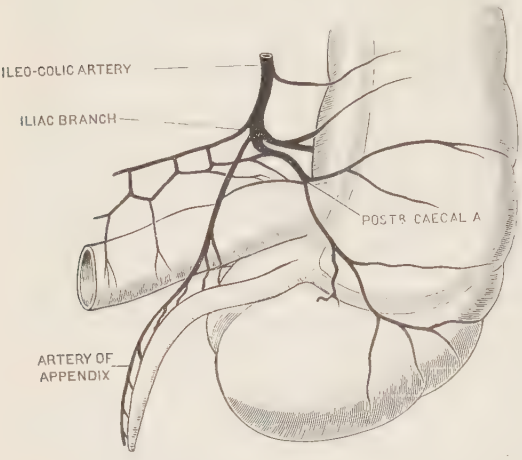

FIG. 916.—THE BLOOD SUPPLY OF THE CÆCUM AND VERMIFORM APPENDIX.

The illustration gives a view of the cæcum from behind. The artery of the appendix, and the three tænia coli springing from the base of the appendix, should be specially noted (modified by Birmingham from Jonnesco).

The **ascending colon**, after crossing the iliac crest, lies deeply in the right lumbar region upon the quadratus lumborum and the right kidney.

The **hepatic flexure** reaches upwards beneath the tenth costal cartilage into the lowest part of the right hypochondrium, where it lies immediately to the right of the gall-bladder, between the liver and the lower half of the anterior surface of the kidney.

The **transverse colon** crosses the upper part of the umbilical region. Not infrequently it forms a U-shaped or a V-shaped loop which reaches for a variable distance below the level of the umbilicus; when the intestines are distended it may ascend in front of the stomach.

The **splenic flexure** reaches upwards behind the greater curvature of the stomach into the left hypochondriac region, as far as the lower extremity of the spleen, from which it is separated by the costocolic fold of peritoneum.

The **descending colon** lies deeply in the left lumbar region, along the lower half of the outer border of the left kidney.

The **iliac** and **pelvic portions** of the **colon** lie respectively in the left iliac fossa and in the true pelvis; the latter is provided with a distinct mesentery which, as it crosses the left ureter and the bifurcation of the common iliac vessels, forms the **intersigmoid peritoneal fossa**. This fossa is sometimes the starting-point of an internal retroperitoneal hernia. The mouth of the fossa looks downwards and to the left; above and to its right is the sigmoid artery. The iliac colon can generally be felt through the abdominal wall as it descends from the crest of the ileum to the inner margin of the psoas muscle. The iliac colon is the part of the bowel which is most frequently opened when it is desired to make an artificial anus. It is exposed through an oblique incision, the centre of which is at the junction of the middle and outer thirds of a line drawn from the umbilicus to the anterior superior iliac spine.

**Kidneys.**—The kidneys, which lie behind the peritoneum, extend higher up than is often supposed, and laterally they do not extend so far away from the spine as is almost invariably depicted; hence it is that, unless enlarged, the kidneys can seldom be felt through the abdominal wall. The right kidney as a rule lies a little lower than the left, as well as a little further away from the mesial plane. The hilum of the right kidney lies 2 in. from the mesial plane; that of the left $1\frac{1}{2}$ in. from the mesial plane. For practical purposes the **hilum** of the kidney may be regarded as opposite a point on the anterior abdominal wall a finger's breadth internal to the tip of the ninth costal cartilage; and a line joining the two hili crosses the vertebral column opposite the disc between the first and second lumbar vertebræ, that is to say, on a level with the transpyloric line. The *highest point* of the kidney is situated two inches from the mesial plane, on a level with a

line crossing the abdomen midway between the xiphisternal and transpyloric planes. The *lowest point* of the kidney reaches down to, or a little below, the infracostal plane.

The student should make himself familiar with the feel of the parts in relation to the kidneys, as far as they can be made out by introducing the hand through a mesial abdominal incision. The lower half of the **right kidney** is covered by the hepatic flexure of the colon; the upper part lies deeply in the hypochondrium, and is felt by thrusting the hand upwards and backwards between the liver and the hepatic flexure of the colon. Between this part of the kidney and the renal surface of the liver is a deep recess which receives its serous covering from peritoneum continued upwards from the upper layer of the transverse mesocolon. Overlapping the hilum and the lower part of the inner border is the descending part of the duodenum, which is crossed by the transverse colon.

The lower half of the **left kidney**, covered by peritoneum continued downwards from the lower layer of the transverse mesocolon, is easily felt in the hollow between the vertebral column and the upper part of the descending colon. It is overlapped by coils of small intestine, and passing transversely outwards in front of it is the left colic artery and its branches. Crossing the left kidney, a little above its middle, is the body of the pancreas, together with the splenic vessels. To reach the part of the kidney which lies above the pancreas, an opening should be made through the gastro-colic omentum and the hand passed upwards behind the stomach into the lesser sac of the peritoneum. Applied to the upper half or more of the outer border of the kidney is the renal surface of the spleen.

The posterior relations of the kidneys will be referred to when dealing with the back.

Outside the true capsule of the kidney is the **adipose capsule**, which is a specialised thickening of the extra-peritoneal fat. It is in this fat that a perinephritic abscess develops, the pus passing backwards into the loin, downwards towards the iliac fossa, or forwards into the extra-peritoneal fat of the anterior abdominal wall.

The **ureters** lie behind the peritoneum covering the psoas muscles; they descend almost vertically in the umbilical region $1\frac{1}{2}$ in. from the mesial plane. At the level of the intertubercular plane they lie in front of the termination of the common iliac arteries, and then pass down into the true pelvis in front of the internal iliac arteries.

**Pancreas.**—The *head of the pancreas* occupies the curve of the duodenum, and lies in the lowest part of the right half of the epigastric region, on a level with the second lumbar vertebra. The *neck*, which crosses the mesial plane opposite the disc between the first and second lumbar vertebræ, lies in the transpyloric plane, while the body lies immediately above that plane. The *tail* lies in the left hypochondriac region. The relations of the pancreas to the transverse mesocolon and to the neighbouring viscera have already been sufficiently referred to.

After opening the abdomen in the middle line, the pancreas is best exposed by passing through the gastro-colic omentum: access to the organ through either the gastro-hepatic omentum or the transverse mesocolon is more limited and therefore less satisfactory.

A pancreatic cyst gives rise to a tumefaction of the abdomen either in the epigastric or in the umbilical region, depending on whether it pushes the gastro-hepatic omentum before it and develops between the liver and stomach, or whether it extends forwards below the stomach. In severe contusions of the abdomen the pancreas may be ruptured against the vertebral column.

**Vessels of the Abdomen.**—The commencement of the **abdominal aorta** and the **cœliac axis** is situated two fingers' breadth above the transpyloric plane. The **superior mesenteric** artery arises a finger's breadth above the transpyloric plane, the **renal arteries** a finger's breadth below it. The **inferior mesenteric artery** arises midway between the transpyloric and the intertubercular plane—that is to say, about 1 in. above the level of the umbilicus. The **abdominal aorta** bifurcates in, or a little to the left of, the mesial plane, on a level with the highest part of the iliac crest, and about $\frac{3}{4}$ in. below the level of the umbilicus.

The **inferior vena cava** lies immediately to the right of the aorta; its most important surgical relation is the right ureter, which lies close to its outer side.

The **common** and **external iliac arteries** may be mapped out by drawing a line, curved slightly outwards, from a point opposite the bifurcation of the aorta to a point midway between the anterior superior iliac spine and the pubic symphysis: the upper third of this line corresponds to the common iliac, the lower two-thirds to the external iliac. The **common iliac veins** lie mainly to the right of the corresponding arteries, the left vein, however, crossing behind the right artery to join its fellow to form the inferior vena cava. The relation of the veins and of the ureters must be borne in mind in ligaturing the common iliac arteries.

The great vessels upon the posterior abdominal wall, along with the adjacent lymphatic vessels and glands, lie in the extra-peritoneal fat, and therefore within the general fascial envelope of the abdomen. Abscesses, originating from the retro-peritoneal lymphatic glands are, therefore, like perinephritic abscesses, extra-peritoneal, but intra-fascial; abscesses of spinal origin, whether lumbar, iliac, or psoas, are, on the other hand, extra-fascial. Abscesses connected with the vermiform appendix are primarily intra-peritoneal; occasionally they ulcerate through the parietal peritoneum and burrow in the extra-peritoneal fat.

## THE MALE PERINEUM.

The male perineum is a heart-shaped space the osseous boundaries of which are the same as those which form the outlet of the pelvis. A line drawn transversely across the perineum between the anterior part of the tuberosities crosses the middle line immediately in front of the anus, and divides the space into an anterior or urinogenital triangle and a posterior or rectal triangle. The **urinogenital triangle** is subdivided into a superficial and deep compartment by the triangular ligament; in the superficial compartment is the root of the penis, which gives rise to a longitudinal fulness upon the surface. Anteriorly, the surface of the urinogenital triangle is continued on to the scrotum, whilst laterally a distinct groove separates it from the inner surface of the thighs. The **central point** of the **perineum** (common tendon of the perineal muscles) is continuous with the centre of the base of the triangular ligament, and lies a finger's breadth in front of the anus. Immediately in front of it, and about 1 in. from the centre of the anus, is the posterior edge of the **bulb** of the **corpus spongiosum**. The *superficial compartment* of the urinogenital triangle is bounded below by the **perineal fascia of Colles** (Fig. 918), which is attached posteriorly to the base of the triangular ligament, and laterally to the margins of the pubic arch. Anteriorly, the fascia of Colles passes

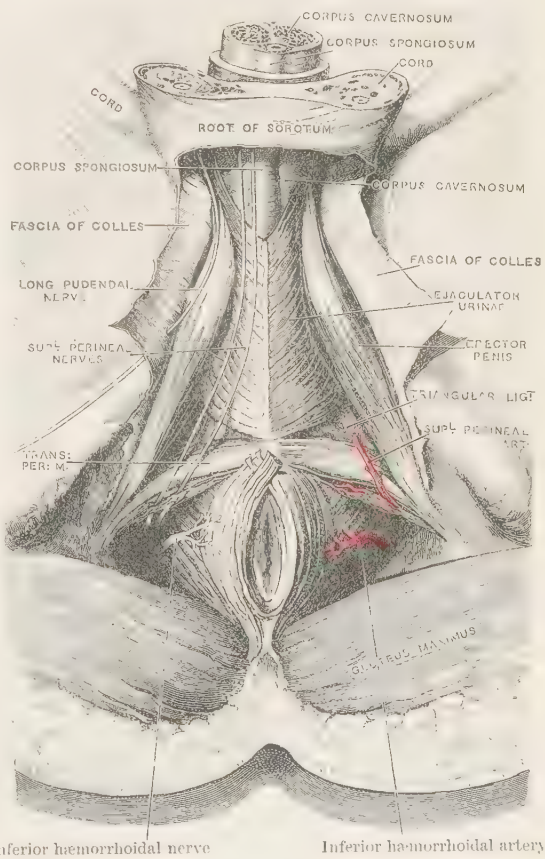

FIG. 918.—DISSECTION OF THE PERINEUM. The scrotum and the penis have been cut transversely across and removed (from Cunningham).

on to the scrotum, the penis, and spermatic cord, to become continuous with the **fascia of Scarpa** upon the front of the abdomen.

When the urethra is ruptured below the anterior layer of the triangular ligament, the course of infiltration of extravasated urine is determined by these attachments; at first, therefore, the urine is confined within this compartment, but gradually travels forwards under the fascia of Colles on to the lower part of the anterior abdominal wall; it is prevented from passing down the front of the thigh by the attachment of Scarpa's fascia to the fascia lata, a little below Poupart's ligament.

The *deep compartment* of the urinogenital division of the perineum corresponds to the interval between the triangular ligament proper and the parietal layer of the pelvic fascia (the so-called superior or deep layer of the triangular ligament). The most important structures which this compartment contains are the membranous portion of the urethra, Cowper's glands, the internal pudic vessels, and the artery to the bulb.

The **membranous part** of the **urethra** lies one inch behind the lower border of the pubic symphysis. When this division of the urethra is ruptured, the extravasated urine, after filling the deep compartment, may reach the superficial compartment by bursting through the triangular ligament where the vessels pierce it; or it may penetrate the parietal layer of the pelvic fascia, infiltrate the perivesical connective tissue and the space of Retzius, and ultimately ascend in the anterior abdominal wall between the fascia transversalis and the parietal peritoneum.

**Cowper's glands**, which lie immediately behind the membranous urethra, are overlapped by the bulb of the urethra, from which they are separated by the triangular ligament. The **internal pudic artery** lies just within the margin of the pubic arch. The **artery to the bulb** runs transversely inwards $\frac{1}{4}$ in. above the base of the triangular ligament, *i.e.* above the level of a line drawn from the front of the tuberosities to the central point of the perineum.

The **male urethra** measures about eight inches from the external to the internal meatus; the narrowest portion is at the external meatus; a second narrowing occurs at the triangular ligament. It is behind these constrictions that a calculus is liable to become impacted. The *most dependent part* of the urethra is the bulbous portion, and it is in this situation that an organic stricture is most frequently met with. The membranous portion of the urethra, situated between the two layers of the triangular ligament, is surrounded by the compressor urethræ muscle, which, when thrown into spasm, may firmly grip an instrument as it is passed into the bladder. *Rupture of the urethra* from a fall on the perineum generally involves the bulbous portion. A *false passage* made during the passage of an instrument generally traverses the floor of the urethra at the triangular ligament; to prevent this the point of the instrument should always be directed upwards, and the handle at the same time depressed as soon as the instrument is felt to encounter the resistance of the triangular ligament. When the *prostate is hypertrophied* the prostatic portion of the urethra is elongated, and the internal meatus may look directly forwards, while if the lateral lobes are unequally enlarged it may deviate laterally. Patients with prostatic hypertrophy are seldom able to completely empty the bladder, on account of the dependent well which exists behind the prostate.

## THE PROSTATE.

The operation of *prostatectomy* has in recent years proved so successful in removing the urinary complications associated with enlargement of the prostate that a fresh impetus has been given to the study of the anatomy of the gland from the surgical point of view. With the body erect the *base* of the prostate lies in a horizontal plane at the level of the middle of the symphysis pubis, while its *apex* lies $\frac{1}{2}$ in. behind and below the sub-pubic angle. It follows, therefore, that the vesical orifice and the base of the prostate are within easy reach of the finger introduced through a supra-pubic cystotomy incision. The *anterior surface* of the prostate lies about $\frac{3}{4}$ in. behind the pubes, to which it is connected by the pubo-prostatic ligaments. Above these ligaments is the *space of Retzius*, occupied by

fatty tissue which passes upwards in front of the anterior wall of the bladder to be continuous with the extra-peritoneal fat. The *posterior surface* of the prostate is related to that part of the rectal ampulla immediately above the anal canal, and is therefore accessible to palpation *per rectum*. Between the rectal and the pelvic fascia covering this surface of the prostate is a loose cellular interval, which is taken advantage of in separating the two organs in the operation of excision of the rectum, and in exposing the posterior surface of the prostate in the operation of perineal prostatectomy. The *lateral surfaces* of the prostate cannot be felt through the rectum; they are related to the anterior or pubo-rectal fibres of the levatores ani, from which they are separated by the lateral portion of the fascial envelope of the gland. The *prostate substance* is made up of branching tubular glands supported by a fibro-muscular stroma. The gland tissue is most abundant in the posterior and lateral aspects of the organ; anteriorly the stroma is more abundant and extends backwards from the capsule to the urethra to form a sort of anterior commissure. By the term "*capsule*" of the prostate is understood the immediate or proper envelope of the gland; this envelope consists of parallel layers of fibro-muscular tissue, continuous with, and forming part of, the stroma of the organ. In some instances it is so thin that the gland tissue reaches almost to its surface, while in other instances it is so thick as to deserve to be regarded as forming the cortical portion of the gland. By the term "*sheath*" of the prostate is meant the fibrous envelope derived from the pelvic fascia. The veins of the *prostatic plexus* lie, not between the capsule and the sheath, but between the lamellæ of the sheath itself. The plexus is arranged in the form of the letter Y, the stem occupying the anterior segment of the sheath, while its limbs embrace the lateral aspects of the base of the gland.

In what is known as "*senile*" *hypertrophy* of the prostate the organ may be uniformly enlarged or the enlargement may chiefly affect one or other of the lateral lobes, one or both of which may enlarge more particularly in an upward direction so as to project into the bladder. This intra-vesical overgrowth may take the form either of a more or less pedunculated projection situated immediately behind the vesical orifice, or it may surround the latter to form a prominent ring-like elevation. As the intra-vesical growth enlarges it makes its way towards the bladder within the ring of the sphincter vesicæ, and, having pushed before, or separated, the internal longitudinal fibres of the bladder, it comes ultimately to be separated from the cavity of the bladder by mucous membrane only. In the operation of *supra-pubic prostatectomy* the true capsule of the prostate is at once reached by simply tearing through the mucous membrane immediately behind the vesical orifice. By keeping close to the capsule, the entire organ, including the capsule, may be enucleated from its sheath. As the latter is markedly thicker and denser in the hypertrophied than in the normal prostate, this enucleation can be accomplished without injuring the veins of the prostatic plexus. As a rule, the only part where any difficulty in the enucleation is encountered is anteriorly, where the capsule is more intimately connected with the sheath by the interposition of a layer of striated longitudinal muscular fibres which pass from the urethra to be continuous with the outer longitudinal fibres of the bladder. In "total" prostatectomy, practically the whole of the prostatic urethra is removed along with the gland. In some instances, instead of removing the entire prostate and its capsule along with the prostatic urethra, the surgeon, by working within the capsule, is able to enucleate each lateral glandular mass either separately or united to its fellow in the form of a horse-shoe shaped mass, the urethra and the anterior commissure being left more or less intact. The cavity, which is left behind after the removal of the prostate, at once contracts owing to the approximation of the bladder and rectum antero-posteriorly, and of the levatores ani laterally.

In perineal prostatectomy the posterior surface of the prostate is exposed by making a horse-shoe shaped incision with the convexity reaching forwards to immediately behind the bulb; laterally the incision sinks into the ischio-rectal fossæ, its extremities ending at the anterior part of the ischial tuberosities (Fig. 918). After reflecting the skin and subcutaneous tissue, the incision is carried through the central point of the perineum and outwards on either side of it through the base of the lower layer of the triangular ligament. The bulb, the superficial transverse perineal muscles, and the triangular ligament (lower layer) are now retracted forwards, and the fibres of the recto-urethral muscle (which connect the anterior wall of the rectal ampulla with the constrictor urethræ) are divided; this allows the anal canal and the lower end of the rectum to be

retracted backwards. The dissection is now carried between the anterior borders of the levatores ani in a forward direction towards the prostate, so as to strike the loose non-vascular space which intervenes between the posterior part of the prostatic sheath and the thin fascia outside the muscular wall of the rectum. The posterior surface of the prostate, covered by its true capsule, is reached by incising the sheath. The prostate, along with its true capsule and the urethra, may either be enucleated from the sheath entire, or the true capsule may be incised as well as the sheath, and the adenomatous masses removed separately. The operation is facilitated by pulling the prostate down into the wound by a special retractor inserted into the bladder through a median incision into the floor of the membranous urethra.

The **epididymis**, which can be felt behind the testicle as an elongated curved body applied vertically to its posterior surface, is especially involved in gonorrhœal and tubercular infections of the testicle. Occupying the posterior part of the spermatic cord is the **vas deferens**, which, when grasped between the finger and thumb, feels like a piece of whip-cord. The **spermatic veins** form a plexus in the substance of the cord, known as the pampiniform plexus; a varicose condition of these veins gives rise to the condition known as *varicocele*. In operating for varicocele the veins are reached by dividing in succession all the coverings of the cord; the deepest covering, viz. the infundibuliform fascia, derived from the fascia transversalis, forms a well-marked fibrous envelope which immediately surrounds the veins and other constituents of the cord. Besides the spermatic artery, the testicle receives its blood supply from the artery accompanying the vas deferens and from the cremasteric branch of the deep epigastric.

The marked swelling which attends *œdema and hæmatoma of the scrotum* is due to the loose and delicate character of the cellular tissue which occupies the space between the dartos muscle and the subjacent membrane derived from the inter-columnar fascia.

The **anus** is situated in the rectal division of the perineum about $1\frac{1}{2}$ in. in front of and below the tip of the coccyx. The skin around the orifice is pigmented and thrown into radiating folds. The painful linear crack or ulcer, known as *fissure of the anus*, generally occupies one of the furrows at the posterior margin of the anus. The skin of the anus is provided with large sebaceous and sweat glands, which are occasionally the site of small and very painful anal abscesses.

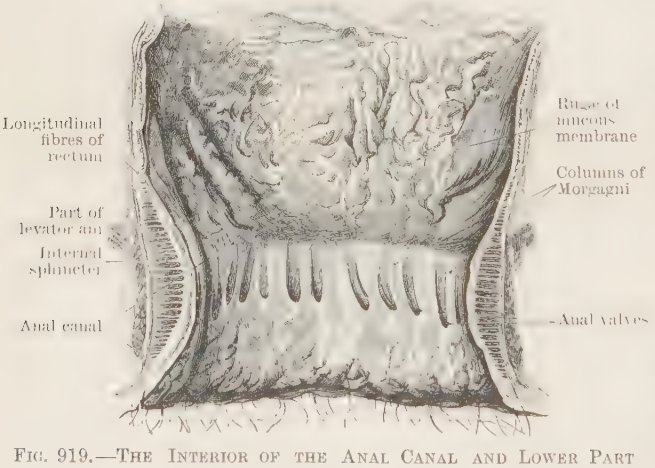

Fig. 919.—The Interior of the Anal Canal and Lower Part of Rectum.

Showing the columns of Morgagni and the anal valves between their lower ends. The columns were more numerous in this specimen than usual (from Birmingham).

On making a *rectal examination* it will be observed that the finger, before it reaches the cavity of the rectum, traverses the narrow or sphincteric portion of the rectum, appropriately named by Symington the **anal canal**. This canal, which is directed from below upwards and forwards, extends from the anal orifice to the ampulla of the rectum, is about 1 in. in length; its upper end is on a level with the inner borders of the pubo-rectal portions of the levatores ani.

*External hæmorrhoids* are developed from the anal folds situated outside the white line corresponding to the muco-cutaneous junction; *internal piles* are developed from the veins of the mucosa at the upper part of the anal canal.

In the upper half of the anal canal are the **columns of Morgagni**. According to

Ball, fissure of the anus is generally caused by the tearing downwards of one of the posterior **anal valves** (Fig. 705) during the passage of a scybalous mass.

According to Birmingham, the pubo-coccygeal fibres of the levator ani close the upper part of the anal canal, whilst the external sphincter closes the remaining part. The internal sphincter, according to the same author, acts probably as a detrusor, its use being to empty the anal canal completely after the passage of each fæcal mass.

The apex of the **ischio-rectal fossa** (Fig. 918), formed by the attachment of the anal fascia to the obturator portion of the parietal pelvic fascia, is directed upwards towards the pelvis, and lies $2\frac{1}{2}$ in. from the surface. The inner wall of the fossa is bounded by the levator ani and coccygeal muscles covered by the anal fascia (Fig. 920); the outer wall by the obturator internus muscle covered by the obturator fascia. An *abscess in the ischio-rectal fossa* should be opened early, otherwise it is liable to burst through the inner wall into the rectum; should it open also upon the skin surface a complete "*fistula in ano*" is formed. When a "fistula in ano" results from the bursting of a submucous abscess of the anal canal the track of the fistula runs either internal to or through the fibres of the internal and external sphincter muscles, and the external or skin opening is, as a rule, close to the anus, while the internal opening is generally within the upper end of the anal canal. Occasionally the ischio-rectal abscess perforates the levator ani towards the apex of the fossa; it then burrows into the peri-rectal cellular tissue of the pelvis, and opens into the ampulla of the rectum. In other cases, again, the abscess starts in the peri-rectal tissue internal to the levator ani, and either bursts into the rectal ampulla or through the levator ani into the ischio-rectal fossa, and so reaches the surface. Or the pus may burrow between the rectum and coccyx, whence it may pass outwards through the great sacro-sciatic foramen behind the parietal pelvic fascia into the buttock; or, by piercing the visceral layer of the pelvic fascia, may reach the extra-peritoneal fatty tissue of the pelvis and ascend in it to form an iliac abscess.

The *lymphatics* from the skin of the anus pass along the perineo-crural folds to the innermost glands of the groin, both inguinal and crural. According to Poirier and Cunéo, those from the region of the white line end in the hypogastric glands which lie in front of the internal iliac artery, while those which issue from the mucous membrane of the upper part of the anal canal and the rectum proper traverse a few minute glands (ano-rectal glands of Gerota) placed between the muscular and fibrous coats of the rectum, alongside the main branches of the superior hæmorrhoidal artery. After traversing these glands they join the glands which lie in relation to the trunk of the superior hæmorrhoidal artery as it lies between the two layers of the pelvic mesocolon.

In making a *rectal examination* the finger should be carried forwards from the tip of the coccyx so as to enter the anus from behind. The finger is then gently pressed upwards and slightly forwards through the sphincteric region in the axis of the anal canal until it reaches the cavity of the rectum, the lower part of which is dilated to form the ampulla. The folds or valves of Houston, three in number, project into the cavity of the bowel in the form of prominent crescentic shelves, which are produced by the three permanent or true flexures into which the rectum is thrown (Birmingham); the lower valve, which may be sufficiently prominent to impede the passage of the finger, must not be mistaken for a pathological condition. Through the anterior wall the finger can palpate from below upwards the bulb of the urethra, the membranous parts of the urethra, Cowper's glands (when inflamed and enlarged), the apex and lateral lobes of the prostate, the vesiculæ seminales (when diseased), and the external trigone of the bladder. With the left forefinger in the rectum, an instrument passed into the bladder can be distinctly felt as it traverses the membranous urethra; as it lies in the prostatic urethra it is separated from the finger by the prostate. Hence, when a *false passage* is made through the bulbous or membranous portion of the urethra, the instrument, if pushed onwards towards the bladder, will be felt immediately outside the rectum between it and the prostate. In the child, owing to the rudimentary condition of the prostate, the instrument is distinctly felt close to the rectum, as it lies in the prostatic as well as in the membranous portion of the urethra. When the prostate is not enlarged the tip of the finger can just reach the external trigone, which is most distinctly felt when the bladder is full. The vesiculæ seminales, indistinctly felt when healthy, may be readily palpated when enlarged and indurated from disease. Through

the lateral wall of the rectum may be palpated the ischio-rectal fossa, the bony wall of the true pelvis, and, when enlarged, the internal iliac lymphatic glands; through the posterior wall the hollow of the sacrum and coccyx, and the lymphatic glands lying in the retro-rectal cellular tissue.

*In the child* rectal examination enables one to palpate, in addition to the structures in the cavity of the true pelvis, those which occupy the lower segment of the abdomen. When the bladder is empty even a small calculus can be readily felt by recto-abdominal palpation.

The distance of the apex of the **recto-vesical pouch** of peritoneum from the anus varies considerably, according to the degree of distension of the bladder and rectum;

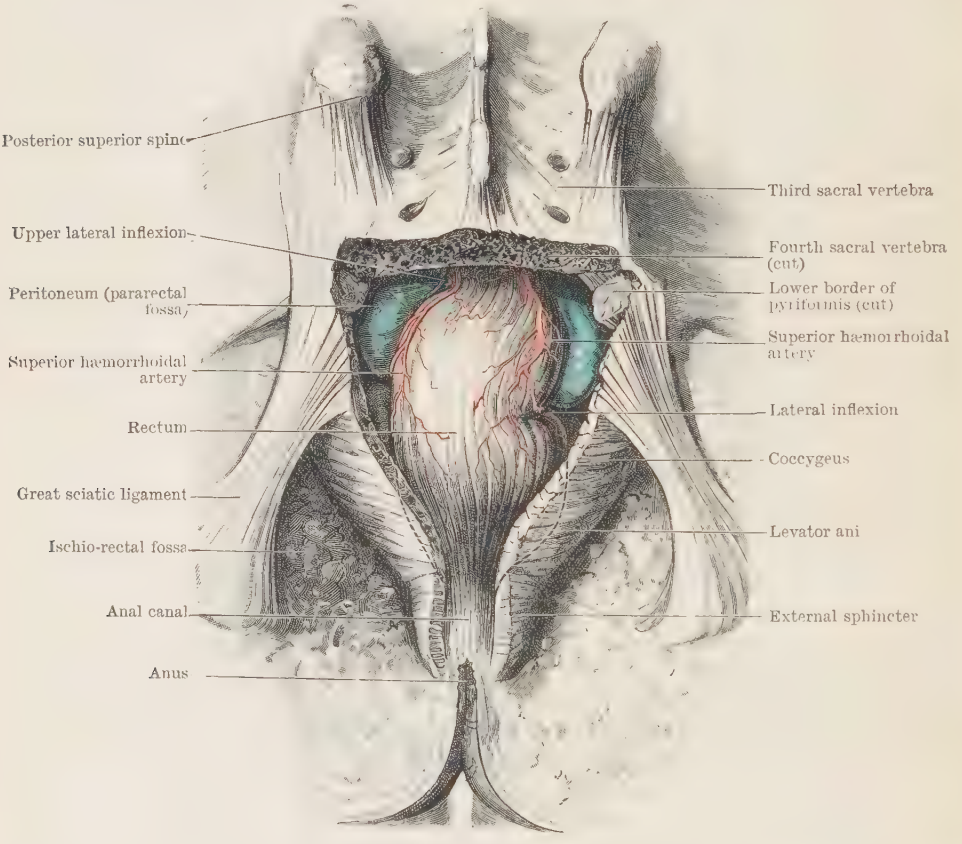

FIG. 920.—THE RECTUM FROM BEHIND.

The sacrum has been sawn across through the 4th sacral vertebra, and its lower part removed with the coccyx. The posterior portions of the coccygei, levatores ani, and of the external sphincter have been cut away. The 'pinching in" of the lower end of the rectum by the inner edges of the levatores ani, resulting in the formation of the flattened anal canal, is suggested in the illustration, which has been made from a formalin-hardened male body, aged thirty. The lateral inflections of the rectum, corresponding to Houston's valves, are also shown (from Birmingham).

when both are empty it reaches to about 2 in. from the anus; when both are distended it is at least one inch higher (Fig. 920). As pointed out by Birmingham, the peritoneum is closely adherent to the rectum above and in front, while at the side and below the connexion is much looser, so that by stripping the peritoneum upwards the greater part, or even the whole, of the rectum may be excised without opening into the peritoneal cavity.

## FEMALE PELVIS.

The external genitals are fully described at page 1195. The external **orifice** of the **urethra**, surrounded by a slight annular prominence of the mucous membrane, is situated about 1 in. behind the clitoris, immediately above the centre of the base

of the vestibule—a smooth triangular area at the anterior part of the vulva, with its sides formed by the labia minora and its base by the anterior margin of the ostium vaginæ. In passing the *catheter* the instrument is directed along the forefinger (introduced just within the ostium vaginæ with the palmar surface towards the symphysis pubis) to the base of the smooth vestibule, where it is tilted slightly upwards so as to bring its point opposite the meatus.

**Bartholin's glands**, about the size of a bean, are placed one on either side of the posterior third of the orifice of the vagina, above the triangular ligament. Their ducts, nearly one inch in length, open posteriorly between the hymen and the posterior commissure (*fossa navicularis*). Abscesses and cysts not infrequently develop in connexion with these glands. The **bulbs of the vagina** are two pyriform collections of erectile tissue situated one upon each side of the vestibule, between the sphincter vaginæ and the anterior layer of the triangular ligament. Rupture of these bodies gives rise to the condition known as *pudendal hæmatocele.*

In making a *vaginal examination* the patient should be placed in the dorsal position, with the thighs well flexed; the index-finger of the right hand is now carried along the fold of the buttock towards the middle line, where it will impinge against the posterior aspect of the **introitus vaginæ**, whence it is inserted upwards and backwards into the canal; to render the examination more thorough the middle finger may also be introduced. When the uterus is in its normal position the **vaginal portion of the cervix uteri** is felt as a knob-like body projecting downwards and backwards into the upper part of the canal. In nulliparæ the os uteri is a small transverse slit, whereas in women who have borne children it is larger and more or less fissured. Above and behind the cervix is the **posterior fornix**, which is in close proximity to the **pouch of Douglas**; this pouch, though normally empty, is the frequent site of displaced abdominal and pelvic organs, and collections of intraperitoneal effusions and exudations. A loaded rectum can be detected through the vagina by the characteristic way in which the contents can be pitted by the finger. In front of the cervix is the shallow **anterior fornix**, through which may be felt the body of the uterus and the base of the bladder, while through the lower half of the anterior vaginal wall the **urethra** may be detected as a cylindrical, cord-like thickening which may be rolled against the lower border of the symphysis. The **ureter**, especially if enlarged, can be recognised through the antero-lateral fornix, by compressing it against the pubic bone.

By the *bimanual examination* the pelvic organs are steadied and pushed downwards towards the pelvic outlet by the pressure of the left hand applied in the hypogastric region, so that they can be more readily reached and palpated by the finger placed in the vagina with its palmar aspect directed upwards. The **ovary** may be felt as a firm body about the size of the end of the thumb by pushing the fingers well up into the lateral fornix towards the lateral wall of the pelvis. In health the ovaries are freely movable. The healthy **Fallopian tubes** cannot, as a rule, be felt per vaginam.

The whole of the **interior** of the **bladder** in the female can be readily seen by reflecting light into it through a speculum introduced into the empty bladder after dilating the urethra. The patient is placed in the genu-pectoral position, so that the bladder may become inflated with air, the coils of intestine being displaced upwards. In the distended condition of the bladder the mucosa has a dull white appearance, except in the region of the trigone, which shows a pale pink injection, when the bladder is contracted the mucosa appears injected throughout. The **ureteral orifices**, placed about one inch apart and connected by a slight transverse ridge (inter-ureteric fold), present the appearance of fine transverse slits situated upon small and somewhat injected elevations of the mucosa. Every minute or so a jet of urine will be seen to issue from the orifice. Having in this way located the ureteral opening, a catheter or bougie may be passed into it along the speculum.

By rectal examination the finger can palpate, from below upwards, the recto-vaginal septum, the cervix uteri, the posterior fornix of the vagina, the apex of the pouch of Douglas, and the body of the uterus. By washing out the rectum and introducing a speculum into the bowel, with the patient in the genu-pectoral position, the rectum becomes inflated with air; the finger can now feel very distinctly the posterior surface of the uterus and the Fallopian tubes, and by running the finger outwards along the prominent fold formed by the utero-ovarian ligament the ovary is also very distinctly felt.

On opening the abdomen by a mesial incision extending from the umbilicus to the pubes, and looking into the pelvis from above after displacing some coils of

the small intestine upwards, the **fundus** of the **uterus**, directed forwards and a little upwards, is seen resting upon the postero-superior surface of the bladder. Behind the uterus is the rectum, and between the two the **pouch of Douglas**, containing the pelvic colon and the lower part of the ileum. The **ovary** lies a little below the level of the brim of the pelvis upon a triangular shelf, bounded in front by the broad ligament, behind and internally by the utero-sacral ligament, and behind and externally by the pelvic wall. When the vermiform appendix overhangs the brim of the pelvis its tip may come into close relation with the right ovary, a condition which often leads to a difficulty in distinguishing an inflammation of that ovary from appendicitis. The **round ligaments** are seen passing forwards and outwards from the anterior aspect of the cornua of the uterus to the internal abdominal rings, which lie immediately in front and to the inner side of the terminations of the external iliac arteries. Below and at the inner side of the round ligament, as it leaves the pelvis, is the **deep epigastric artery**. By pulling the uterus upwards the attachments of the **broad ligament** to the floor and lateral walls of the pelvis are brought into evidence, as also are the utero-vesical and recto-vaginal peritoneal pouches; the former is shallow, while the deepest part of the latter covers the upper fourth of the posterior wall of the vagina, and comes into relation, therefore, with the posterior fornix.

The **ureter** crosses the brim of the pelvis in front of the bifurcation of the common iliac artery $1\frac{1}{2}$ in. external to and a little below the centre of the sacral promontory. The corresponding point on the anterior abdominal wall is at the junction of the outer and middle thirds of a line joining the anterior superior spines of the ilium. After crossing the termination of the common iliac artery from without inwards the ureter curves downwards and forwards behind the peritoneum of the postero-lateral wall of the true pelvis; in front of it are the Fallopian tube and ovary. Before reaching the bladder it enters the parametric connective tissue, in which it curves downwards, forwards, and inwards about three-quarters of an inch external to the lateral aspect of the cervix uteri.

The **uterine artery** in the first part of its course runs downwards and forwards a little external to the ureter; at the level of the internal os it curves inwards in front of the ureter and then divides into uterine and vaginal branches.

In the operation of *hysterectomy* care must be taken not to injure the ureter; it is important, therefore, to keep in mind its relation more especially to the uterine artery and to the cervix uteri.

The **ovarian artery** enters the pelvis between the layers of that portion of the broad ligament known as the **infundibulo-pelvic ligament**; it is here that the vessel may be most readily ligatured in abdominal hysterectomy, and in ovariotomy.

## THE BACK.

In the middle line of the back is the **spinal furrow**, which is deepest in the lower dorsal and upper lumbar regions, where the erectores spinæ muscles are most prominent. Over the upper sacral region, where the erectores spinæ muscles are tendinous, is a flattened area forming an equilateral triangle, the angles of which correspond respectively to the posterior superior spines of the two iliac bones and the third sacral spine. The **vertebral spines** can be palpated at the bottom of the spinal furrow; they become more distinct when the spine is flexed, and, as pointed out by Holden, they become mapped out by reddened areas when friction is applied along the furrow. The identification and counting of the spines will be facilitated if it be remembered that the first dorsal is more prominent than the vertebra prominens (seventh cervical), that the third dorsal is on a level with the root of the spine of the scapula, the seventh dorsal with its inferior angle, the fourth lumbar with the highest part of the iliac crest, and the second sacral with the posterior superior iliac spine.

Above the spine of the scapula is the **suprascapular region**, which is padded by a thick mass of muscle consisting of the supra-spinatus and levator anguli scapulæ, covered by the upper part of the trapezius; the two latter muscles may be thrown into relief by shrugging the shoulders.

In the **interscapular region** are the rhomboid muscles which are thrown into prominence by bracing back the shoulders.

Below the inferior angle of the scapula the last five ribs can readily be felt external to the erector spinæ muscle; when the twelfth rib does not reach beyond this muscle, the eleventh rib will be mistaken for it, unless the ribs be counted from above downwards.

The **lower border of the trapezius** is indicated by a line extending upwards and outwards from the twelfth dorsal spine to the root of the spine of the scapula; the **upper border of the latissimus dorsi** by a line extending from the sixth dorsal spine transversely outwards across the angle of the scapula. Between these two muscles and the lower part of the vertebral border of the scapula is a triangular area, the floor of which is formed by the rhomboideus major muscle and the sixth costal interspace.

The outer border of the **erector spinæ** is indicated on the surface by drawing a line from a point on the iliac crest $3\frac{1}{2}$ in. (four fingers'-breadth) from the middle line, upwards and slightly outwards to the angles of the ribs. The outer border of the **quadratus lumborum,** which passes upwards and slightly inwards, lies a little external to that of the erector spinæ at the crest, and a little internal to it at the twelfth rib.

The anatomy of the muscles and fasciæ which complete the abdominal wall between the last rib and the iliac crest is of great importance in connexion with operations in the **region of the loin.** The space between the last rib and the iliac crest varies greatly according to the length of the former, and according to the general shape of the chest and slope of the ribs. As a rule, the **tip of the twelfth rib** lies about two inches vertically above the centre of the iliac crest. From a surgical point of view the costo-iliac space may be said to be limited internally by the outer edge of the erector spinæ, and, more deeply, by the tips of the transverse processes of the lumbar vertebræ, while externally it is bounded by the posterior free border of the external oblique, and, more deeply, by the line of reflection of the peritoneum from the colon on to the lateral wall of the abdomen. The space is roofed over by the latissimus dorsi, except below, where a narrow triangular interval is left between its outer border and the posterior border of the external oblique, the base of the triangle being formed by the crest of the ilium, a little behind its centre. This triangle (Fig. 275, p. 358), known as the "**triangle of Petit**," represents a weak area through which a lumbar abscess may come to the surface, and through which a lumbar hernia occasionally develops. On removing the latissimus dorsi and the lower part of the thin serratus posticus inferior, another triangle will be exposed, which constitutes a second weak area in the loin; it is bounded above by the last rib, internally by the outer border of the erector spinæ, and externally by the posterior muscular fibres of the internal oblique; the floor of the triangle is formed by the aponeurosis of origin of the transversalis abdominis muscle. At the outer border of the quadratus lumborum this aponeurosis splits into three layers to form two compartments, the anterior enclosing the quadratus lumborum and the posterior the erector spinæ.

**Kidneys.**—By retracting inwards the erector spinæ and dividing the posterior fibres of the three abdominal muscles, along with the outer fibres of the quadratus, the kidney may be exposed, with the colon lying vertically in front of its outer border (Fig. 921). The upper limit of the kidney is indicated by a line drawn transversely across the loin opposite the eleventh dorsal spine, the lower limit by a line on a level with the third lumbar spine. The upper extremity reaches to the eleventh rib; the lower, which lies immediately external to the tip of the transverse process of the third lumbar vertebra, reaches to within $1\frac{1}{2}$ to 2 in. of the crest of the ilium. About a third of the kidney lies above the lower margin of the twelfth rib. The left kidney usually lies about $\frac{1}{2}$ in. higher than the right. The most external point of the outer border lies 4 in. from the middle line, while the hilum lies $1\frac{1}{2}$ in. external to it in front of the interval between the tips of the transverse processes of the first and second lumbar vertebræ.

The psoas muscle intervenes between the postero-internal surface of the kidney and the transverse processes, and protects the organ from injury by a blow directed

from the front. Between the upper end of the kidney and the eleventh and twelfth ribs is the diaphragm and the posterior costo-diaphragmatic reflection of the pleura (Fig. 921). The relations of the pleura to the last rib have already been considered (p. 1238).

Posteriorly the course of the upper part of the **ureter** may be indicated by a line drawn vertically upwards from the posterior superior iliac spine to the level of the second lumbar spine; the deep guides are the tips of the transverse processes of the second, third, and fourth lumbar vertebræ, covered by the psoas muscle.

A needle passed through the inner extremity of the eleventh intercostal space will transfix the **suprarenal body**.

The pus of a **perinephritic abscess** occupies the extraperitoneal fatty layer (peri-

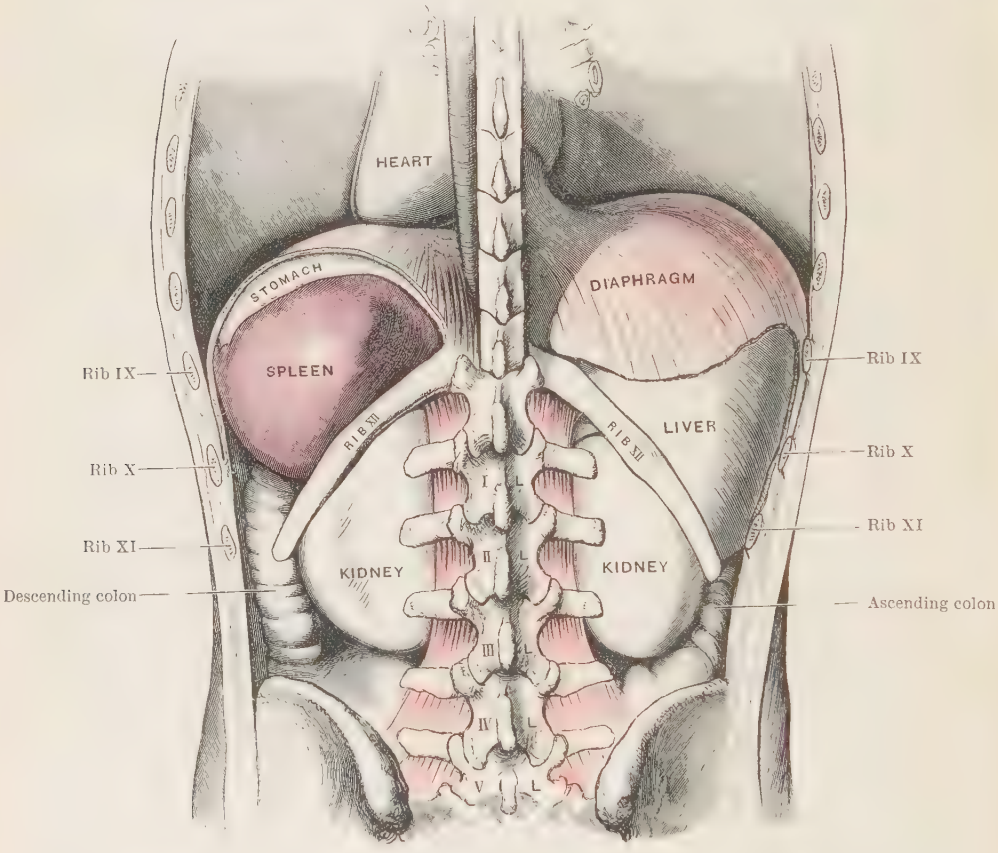

FIG. 921.—DISSECTION OF THE SPLEEN, LIVER, AND KIDNEYS FROM BEHIND, IN A SUBJECT HARDENED BY FORMALIN-INJECTION (from Cunningham).

renal fat), and lies, therefore, within the fascial envelope of the abdomen; the pus in a **psoas abscess**, on the other hand, lies external to the fascia. In opening a psoas abscess from behind, a vertical incision is made in the angle formed by the outer border of the erector spinæ and the crest of the ilium; in the deeper part of the dissection the surgeon should keep close to the front of the transverse process of the fourth lumbar vertebra.

**Diaphragm, Liver, Stomach, and Large Intestine.**—Posteriorly the **right arch of the diaphragm** and the right lobe of the liver extend upwards to the level of the angle of the scapula (eighth rib), while the **left arch** and the fundus of the stomach lie one inch lower (eighth interspace); the central tendon reaches up to the eighth dorsal spine. The **right lobe of the liver** is covered posteriorly by the eighth to the twelfth ribs, and is overlapped by the base of the right lung as far as a line drawn horizontally outwards from the tenth dorsal spine; hence, posteriorly,

the upper limit of the liver cannot be defined by percussion, and its lower limit merges into the dulness of the loin muscles and kidney.

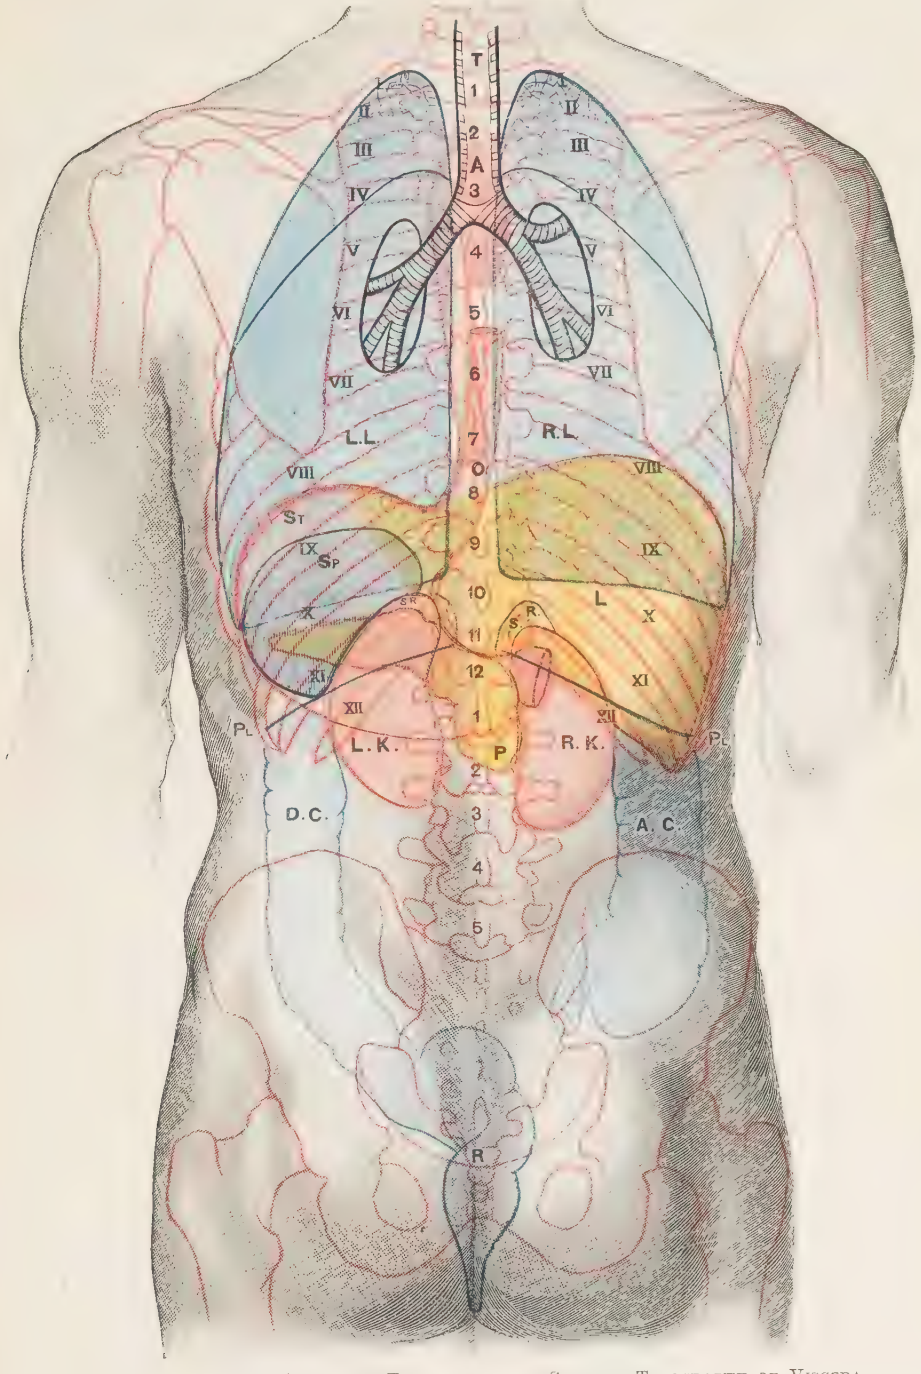

Fig. 922.—Posterior Aspect of Trunk, showing Surface Topography of Viscera.

| | | | | | |
|---|---|---|---|---|---|
| T. | Trachea. | Sp. | Spleen. | P. | Pancreas. |
| A. | Aorta. | L. | Liver. | Pl. | Pleura. |
| L.L. | Left lung | S.R. | Suprarenal body. | D.C. | Descending colon. |
| R.L. | Right lung. | L.K. | Left kidney. | A.C. | Ascending colon. |
| St. | Stomach. | R.K. | Right kidney. | R. | Rectum. |

The **cardiac orifice of the stomach** lies one inch to the left of the ninth dorsal spine. The cardiac portion, overlapped by the ninth to the twelfth ribs, extends

upwards to the level of the eighth dorsal spine, one inch below the angle of the scapula. The **pyloric portion** crosses the mesial plane opposite the twelfth dorsal and first lumbar spines, the **pylorus** itself being situated one inch to the right of the twelfth dorsal spine. The **lesser curvature** lies to the left of and below the tenth and eleventh dorsal spines.

Viewed from behind, the **large intestine** on both sides overlaps the outer border of the kidneys and lies parallel to the outer border of the erectores spinæ muscles. The peritoneum is reflected from the colon on to the posterior abdominal wall along a line drawn vertically upwards from the centre of the iliac crest. The **splenic flexure**,

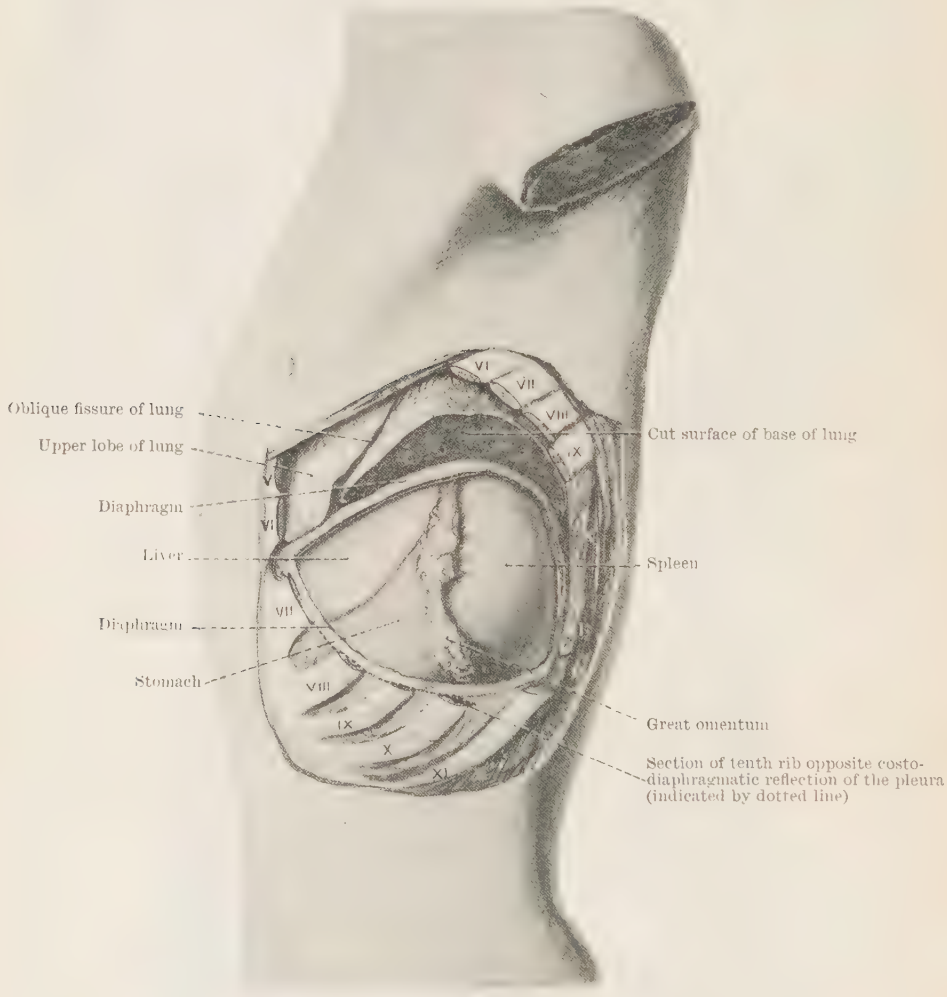

FIG. 923.—DISSECTION OF THE LEFT HYPOCHONDRIUM TO SHOW THE RELATIONS OF THE SPLEEN TO THE LATERAL WALL OF THE CHEST, THE DIAPHRAGM, AND THE ADJACENT VISCERA. In addition to the portions of ribs, there has been removed a part of the base of the left lung, and a window has been made in the diaphragm almost down to the level of the costo-diaphragmatic reflection of the pleura.

which reaches up to the level of the twelfth dorsal spine and the tenth rib, lies about five inches above the iliac crest. The **hepatic flexure** lies on a level with the first lumbar spine.

**Spleen.**—The *spleen*, situated in the left hypochondrium behind the cardiac end of the stomach, is overlapped by the ninth, tenth, and eleventh ribs, the long axis of the organ corresponding approximately to that of the tenth rib. Between the upper third of the spleen and the chest wall (pleura and diaphragm intervening) is the base of the left lung, the lower margin of which crosses the organ horizontally at the level of the tenth dorsal spine. The costo-diaphragmatic reflection of the

pleura reaches down as far as the inferior angle of the spleen. The upper limit of the organ cannot therefore be defined by percussion; and unless enlarged, or displaced downwards, the spleen cannot be punctured from behind without traversing the pleural as well as the peritoneal cavity.

Of the *three angles* of the spleen, the *posterior or vertebral* lies at the same level as the lower margin of the lung, $1\frac{1}{2}$ in. external to the tenth dorsal spine. The *inferior angle* lies opposite the eleventh intercostal space on a level with the first lumbar spine, in a line drawn vertically upwards from a point one inch behind the centre of the iliac crest. This angle is situated behind the upper part of the descending colon immediately external to the middle of the outer border of the kidney. The *anterior angle* is at the level of the ninth interspace in the mid-axillary line. Having placed a mark on the skin opposite these three angles the organ is mapped out on the surface as follows:—The *posterior or renal border* is obtained by joining the posterior and inferior angles; this border, which gives the key to the position of the spleen, will be found to follow the eleventh intercostal space. The short *antero-inferior border* corresponds to a line joining the anterior and the inferior angles; it is related to the splenic flexure of the colon, and may therefore be termed the *colic border*. Commencing at the vertical angle, the so-called *anterior border* is at first arched upwards, the summit of the arch reaching to the level of the upper border of the ninth rib in the scapular line; thence it is continued downwards and forwards across the posterior axillary line as the "anterior crenated border" to the anterior angle. The upper arched portion lies parallel to and about one inch below the highest part of the fundus of the stomach. The only parts of the splenic outline which can be defined by percussion are the lower crenated part of the anterior border, the anterior angle, and the short postero-inferior or colic border; and it is these parts which may be felt below the costal margin when the organ is considerably enlarged.

In excising the spleen it is important to remember that the splenic vessels lie between the two layers of the lieno-renal ligament, and not in the gastro-splenic omentum, which contains the vasa brevia. In a floating spleen these two peritoneal ligaments are elongated to form a distinct pedicle.

**Pancreas.**—The head of the **pancreas** lies opposite the last dorsal and first lumbar spines; the tail lies at the same level as the splenic flexures of the colon, a little above the inferior basal angle of the spleen.

TABLE INDICATING THE LEVEL OF THE MORE IMPORTANT STRUCTURES IN RELATION TO THE SPINES OF THE VERTEBRÆ.

| Spines of Vertebræ. | Origins of Spinal Nerves. | Level of other Structures. |

**Spinal Cord.**—The spinal cord ends opposite the lower border of the first lumbar spine; in the infant it reaches to the interval between the second and third lumbar spines. The *cervical enlargement* which corresponds to the lower four cervical and the first two dorsal segments ends opposite the seventh cervical spine. The *lumbar enlargement* lies opposite the last three dorsal spines. The five lumbar segments are opposite the ninth, tenth, and eleventh dorsal spines, while the five

sacral segments extend from the lower border of the eleventh dorsal to the lower border of the first lumbar spine.

The **sub-dural space** extends down to the level of the second sacral spine. In performing the operation of *lumbar puncture* (Quincke) a fine trochar and cannula is introduced into the sub-arachnoid space below the level of the cord, the puncture being made $\frac{1}{4}$ to $\frac{1}{2}$ in. to one side of the interspinous ligament in the interval between the third and fourth or fourth and fifth lumbar spines. The instrument should be directed inwards towards the mesial plane and very slightly upwards. In the adult the distance of the thecal sac from the surface is about 2 in., in the infant $\frac{3}{4}$ in.

**Fracture-dislocations of the spine** are commonest in the lower cervical and dorso-lumbar regions; that is to say, where the movable cervical and lumbar regions join the more fixed dorsal region. The spinal column above the injury is generally displaced forwards, so that the spinal cord is often severely lacerated or completely torn across by the upper end of the portion of the column below the fracture. It is important to remember that in consequence of the shortness of the cord as compared with the spine, the origins of the spinal nerves are at a higher level than their exits from the spinal canal. The distance between their origins from the cord and their exits through the intervertebral foramina becomes greater the further down we descend, the lowest nerve trunks running almost vertically downwards. The cervical nerves leave the spinal canal *above* the vertebræ after which they are named; the dorsal, lumbar, and sacral nerves, on the other hand, leave the canal *below* the correspondingly named vertebræ.

To understand the effect of **lesions of the cord**, it is necessary to be familiar with the sensory and motor distributions of the various spinal segments (see Figs. 487, p. 611, and 489, p. 615). Transverse lesions of the cord *above the fifth cervical spine* (that is, above the disc between the fourth and fifth cervical vertebræ) are quickly fatal from paralysis of respiration, as the phrenic nerve arises mainly from the fourth segment. In transverse lesions of the cervical enlargement the *cutaneous insensibility* does not extend higher than a transverse line at the level of the second intercostal space. The diagnosis of the particular segment involved is arrived at by testing the motor and sensory functions of each segment. The sensory areas corresponding to the *lower four cervical* and the *first two dorsal segments* occupy the upper extremities, and are placed in numerical order from the radial to the ulnar side of the limb. The sensory area corresponding to the *second*, *third*, and *fourth cervical segments* occupy the occipital region of the scalp, the back of the auricle, and the masseteric region, the whole of the neck, and the shoulders and upper part of the chest down to a horizontal line at the level of the anterior end of the third intercostal space. In total transverse lesion of the cord in the *dorsal region*, the upper limit of the anæsthesia is horizontal, and reaches to the level of the terminations of the anterior primary divisions of the spinal nerves which arise from the spinal segment opposite the vertebral injury. Hence the upper limit of the anæsthesia is at a much lower level than that of the injured vertebra. For example, a fracture-dislocation at the level of the eighth dorsal vertebra involves the origin of the tenth dorsal nerve which ends at the level of the umbilicus. The sensory zone corresponding to the *fifth dorsal segment* is at the level of the nipples, that of the *seventh dorsal segment* is at the level of the ensiform cartilage, that of the *tenth* at the level of the umbilicus, while that of the *twelfth* reaches down anteriorly to the upper border of the symphysis. The sensory areas corresponding to the lumbar and sacral segments are seen in Figs. 487 and 489.

## THE UPPER EXTREMITY.

### THE SHOULDER.

The bony landmarks of the shoulder must be systematically examined in all injuries about this region. The **inner extremity** of the **clavicle** is prominent; its articulation with the sternum forms essentially a weak joint which is liable to be dislocated, especially from blows upon the outer part of the shoulder which drive the inner end of the clavicle forwards against the weak anterior sterno-clavicular ligament. The **shaft** of the **clavicle**, subcutaneous throughout, is weakest at the junction of its two curves; it is in this region that the bone is so frequently

fractured as the result of force transmitted through it to the trunk. The displacement of the outer fragment varies according to whether the break takes place internal or external to the coraco-clavicular ligament; in the former case the weight of the upper extremity, acting through the coraco-clavicular ligament, pulls the outer fragment downwards; when the fracture is external to the ligament, the outer end of the clavicle rotates forwards, but there is no downward displacement. The **outer end** of the **clavicle** is on a plane posterior to its inner end, so that the shoulder is braced backwards away from the thorax; hence in fractures of the clavicle, both inside and outside the coraco-clavicular ligament, the point of the shoulder rotates forwards and inwards. The **acromio-clavicular articulation** is somewhat difficult to feel; the groove which corresponds to it runs in the sagittal direction, and lies $1\frac{1}{4}$ in. internal to the outer border of the acromion, and immediately external to a slight prominence upon the outer extremity of the clavicle. When this joint is dislocated the clavicle almost invariably overrides the acromion, and the summit of the shoulder presents a somewhat conical or "sugar-loaf" appearance.

The **tip** of the **acromion** looks directly forwards, and lies a finger's-breadth external to and a little in front of the outer extremity of the clavicle. The **outer border** of the **acromion** can readily be followed to its junction with the spine of the scapula, and the latter to its root, which is situated on a level with the third dorsal spine. The **inner border** of the **acromion** and the posterior border of the outer end of the clavicle meet at an angle into which the point of the finger can be pressed. The **upper angle** of the **scapula**, covered by the trapezius and the supraspinatus muscles, is too deeply placed to be palpated distinctly. The **inferior angle**, and the **internal border**, from the root of the spine downwards, form visible prominences which are readily felt; the former overlies the seventh intercostal space on a level with the seventh dorsal spine, while the latter lies a little internal to the angles of the ribs.

To elicit crepitus in a transverse fracture of the scapula below the spine, the surgeon stands behind the patient and grasps the upper fragment by placing the forefinger upon the coracoid and the thumb upon the spine, while with the other hand he grasps the inferior angle; the two fragments are then moved the one upon the other.

The **tip** of the **coracoid process** may be felt by pressing the finger firmly upon the anterior border of the deltoid at a point one inch below the junction of the middle and outer thirds of the clavicle. Internal to the coracoid is a triangular depression which corresponds to the upper end of the interval between the clavicular fibres of the pectoralis major and deltoid muscles. Behind this triangular depression are the termination of the cephalic vein, a lymphatic gland, the first part of the axillary vessels, and the cords of the brachial plexus. By firm pressure in this situation the pulsation of the **axillary artery** can be felt, and by further pressure the circulation in the vessel can be arrested by compressing the artery against the second rib. The *first part* of the axillary artery may be cut down upon either by a transverse incision through the clavicular origin of the pectoralis major, or by a longitudinal incision in the interval between this muscular slip and the deltoid. The **companion vein** lies in front of, as well as to the thoracic side of, the artery, thus adding to the difficulty of exposing the vessel. In fractures of the middle third of the clavicle the subclavian vessels are protected by the soft pad formed by the subclavius muscle.

The **upper end** of the **humerus** covered by the deltoid gives rotundity to the shoulder. The **greater tuberosity** projects beyond the acromion, and constitutes the most external bony landmark of the shoulder. When the head of the bone is dislocated, the outer border of the acromion then becomes the most external bony landmark, and the shoulder presents a square contour. The **lesser tuberosity**, small but conical, can be felt through the deltoid. Pointing directly forwards, it lies one inch external to and a little below the level of the tip of the coracoid process. In examining the upper end of the humerus for fracture, the tuberosities should be grasped between the finger and thumb of one hand, while the flexed elbow is rotated with the other hand. The **head** of the **humerus** has the same direction as the internal condyle; its lower part can be palpated through the axilla, the arm

being meanwhile abducted, to bring the head in contact with the under surface of the capsule. It is through this, the weakest part of the capsule, that the head is driven in the common varieties of dislocation of the shoulder, viz. those due to forcible abduction. The **upper epiphysis** of the humerus includes the head and the greater part of the tuberosities. The capsule is mainly attached to the epiphysis; hence, in children, we find that separation of the upper epiphysis takes the place of dislocation. Disease in the upper end of the diaphysis does not necessarily involve the cavity of the joint. The **bicipital groove** of the humerus, which lies immediately external to the lesser tuberosity, may be mapped out upon the surface by drawing a line, two inches in length, downwards along the axis of the humerus from the tip of the acromion. When there is *effusion into the joint*, the arm becomes slightly abducted, and there is fulness in front, along the line of the long tendon of the biceps. With the elbow at the side the inferior part of the capsule of the shoulder-joint is loose and folded upon itself to form a dependent pocket; if, after an injury, the arm be retained too long in this position, the patient may be unable to abduct the arm in consequence of the formation of adhesions in and around the pouch. To evacuate pus from the shoulder-joint, the integuments, deltoid, and capsule should be cut into by an incision passing vertically downwards from the tip of the acromion.

## THE AXILLA.

The **anterior fold** of the **axilla**, formed by the lower border of the pectoralis major, extends from the fifth rib to the middle of the anterior border of the deltoid. With the arm abducted, the interval between the sternal and clavicular fibres of the pectoralis major is indicated by a slight groove extending downwards and outwards from the inner end of the clavicle. The sternal fibres, along with the pectoralis minor, are removed in a complete operation for malignant disease of the breast, the pectoral branches of the thoracic axis artery being secured as they cross the interval between the sternal and clavicular portions of the greater pectoral. The **posterior fold** of the **axilla**, formed by the latissimus dorsi and the teres major muscles, is on a lower level than the anterior fold, and leaves the chest a little in front of the inferior angle of the scapula. Between the two folds, and running in the long axis of the limb, from the axilla to the middle of the upper arm, is the prominence of the **coraco-brachialis muscle**. The pulsations of the **third part of the axillary artery** may be felt in the furrow immediately behind this prominence at the junction of the anterior and middle thirds of the outer wall of the axilla.

**Female Mamma.**—The breast tissue proper is arranged to form a central portion, the *corpus mammæ*, and a peripheral portion, made up of branching processes which radiate into the paramammary fat and become continuous ultimately with the connective tissue septa of the subcutaneous fatty tissue. The mamma, therefore, has no distinct capsule. In the young adult nullipara, the corpus mammæ is compact and well defined, and contains but little intramammary fat, while the peripheral processes are relatively small. In multipara, the corpus mammæ contains more fat, and the peripheral processes extend more widely into the paramammary fat.

The arrangement and extent of the parenchyma can be well seen by treating the breast with a 5 *per cent solution of nitric acid*. If slices of the fresh organ be placed in this solution for a few minutes and then washed under running water, the albumen of the epithelial cells of the parenchyma is coagulated, while the connective tissue is rendered translucent and somewhat gelatinous. The *ultimate lobules* of the *parenchyma* now appear as little (1 to 2 mm.), dull, opaque, white, sago-like bodies, arranged in grape-like clusters around the finer branches of the ducts.

The parenchyma is prolonged into the peripheral processes, into the suspensory ligaments of Cooper, and into the loose retromammary cellular tissue and pectoral fascia. The breast tissue, therefore, has a much wider distribution than was formerly supposed. Vertically, it extends from the second rib to the sixth costal cartilage at the angle where it begins to ascend towards the sternum; horizontally, from a little within the lateral border of the sternum, opposite the fourth rib, to the fifth rib in the midaxillary line. The *inner hemisphere* of the mamma rests

almost entirely on the pectoralis major; at its lowest part it slightly overlies the upper part of the aponeurosis covering the rectus abdominis muscle. The *upper quadrant* of the *outer hemisphere* rests upon the greater pectoral, on the edge of the lesser pectoral, and to a slight extent on the serratus magnus, upon which it extends upwards into the axilla ("axillary tail" of Spence) as high as the third rib, where it comes into relation with the thoracic group of axillary lymphatic glands. The *remainder of the outer hemisphere* rests almost entirely upon the serratus magnus, except the lowest part, which overlaps the digitations of the external oblique arising from the fifth and sixth ribs. It follows, therefore, that *fully one-third of the whole mamma lies inferior and external to the axillary border of the pectoralis major muscle.* The surgeon must cut beyond the above limits if he wishes to remove the whole of the mammary tissue.

The axillary fascia resists the spontaneous rupture of an axillary abscess, which, therefore, tends to spread upwards beneath the pectorals, and towards the root of the neck. To open the abscess the incision should be made upon the inner wall, behind, and parallel to, the long thoracic artery, which runs under cover of the anterior fold.

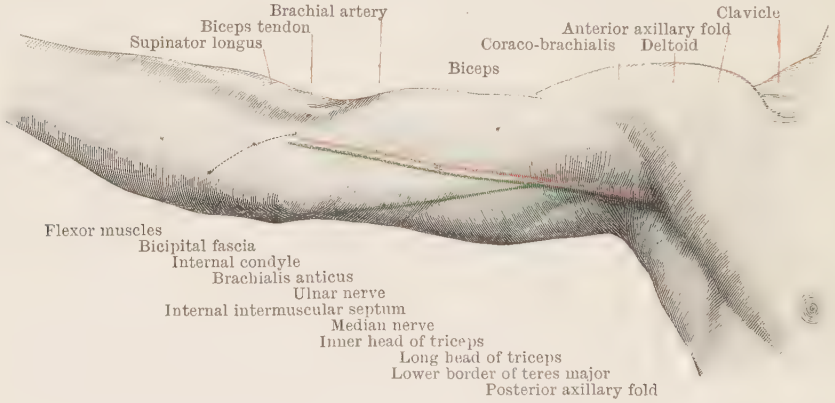

Fig. 924.—Axilla, Inner Aspect of Upper Arm and Elbow.

The **axillary lymphatic glands** vary greatly in size and number; many are no larger than a pin's head. In the female some of them undergo an adipose functional involution, whereby they come to resemble fat lobules. In health one or two glands can usually be felt by thrusting the fingers upwards and inwards beneath the anterior fold, the arm being only slightly abducted, so as not to stretch the axillary fascia. The *central group* (Leaf), embedded in the fat immediately beneath the axillary fascia, become inflamed in poisoned wounds of the upper extremity. The same group, along with the *pectoral group* (related to the inner wall of the axilla, at the lower border of the pectoralis minor), are usually the first to become diseased in malignant affections of the breast. When the disease is more advanced the *posterior* (subscapular) and the *apical* (subclavicular) groups are generally affected as well; and Rotter has shown that in a considerable porportion of cases diseased glands are to be found in the *retro-pectoral fascia, i.e.* between the pectoralis major and minor and above the latter muscle on the first intercostal space in relation to the small superior thoracic artery. In operating for malignant disease of the breast, the surgeon removes, in addition to the whole breast and the greater part of the skin over it, both pectoral muscles (with the exception of the clavicular fibres of the pectoralis major), all the axillary lymphatic glands, and, as far as possible, all the fat and fascia, including the sheath of the axillary vein. It must be remembered that the lower part of the axillary vein lies immediately underneath the deep fascia of the outer wall of the axilla; in cleaning the inner wall the long thoracic nerve must not be injured; and in removing the posterior group of lymphatic glands the long subscapular nerve, which accompanies the subscapular vessels, must be avoided, as it is doubly important to retain the action of the latissimus dorsi after removing the pectorals. The writer has so frequently met with disease in these retro-pectoral glands, that he is convinced of the necessity of removing the pectoral muscles.

## THE UPPER ARM.

The anterior and posterior borders of the **deltoid** may be traced from the shoulder girdle to the insertion of that muscle. The surface relations of the anterior border have already been referred to; the posterior border forms a well-marked and important landmark as it crosses the angle between the axillary border of the scapula and the upper part of the shaft of the humerus. By making an incision along this part of the posterior border of the deltoid, and retracting the edge of the muscle upwards and outwards, we expose the **surgical neck** of the **humerus**, the quadrilateral opening in the posterior wall of the axilla transmitting the posterior **circumflex artery** and the **circumflex nerve**; a little lower down is the musculo-spiral nerve. The **coraco-brachialis**, the guide to the upper half of the brachial artery, forms a prominence occupying the upper half of the *internal bicipital furrow*. Traced downwards the internal bicipital furrow widens out into an elongated triangle. This triangle, which may be termed the *internal supracondyloid triangle*, becomes continuous below with the inner part of the triangle in front of the bend of the elbow, and is limited posteriorly by the internal intermuscular septum, which may be felt as a cord-like band extending upwards from the internal condyle; the

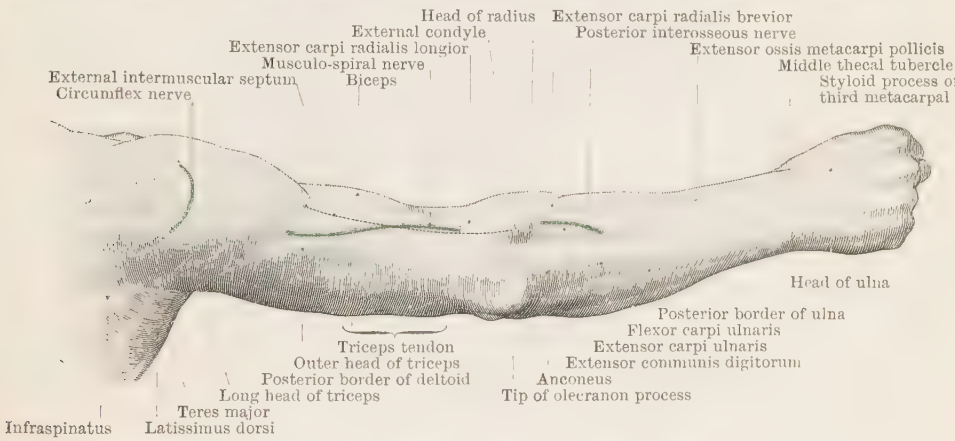

Fig. 925.—Extensor Aspect of Upper Limb.

floor of the space is formed by the inner part of the brachialis anticus. Within the triangle are the following important structures, enumerated from without inwards, viz.: the **brachial artery**, the **median nerve**, the **lower part of the basilic vein**, the **internal cutaneous nerve** and the **supracondyloid lymphatic glands**, two or three in number. Extending upwards from the external condyle to the insertion of the deltoid is the external intermuscular septum, which is pierced at the junction of its upper and middle thirds by the **musculo-spiral nerve**. Between the external intermuscular septum and the outer edge of the biceps is the ill-defined *external bicipital furrow*, the floor of which is formed by a strip of the brachialis anticus, and, nearer the elbow, by the supinator longus and extensor carpi radialis longior.

The posterior compartment of the upper arm is occupied by the **triceps**, the *long head* of which can be traced upwards to the axillary border of the scapula in front of the posterior border of the deltoid and behind the posterior fold of the axilla. The *outer head* of the triceps, after emerging from under cover of the lower part of the posterior border of the deltoid, is continued obliquely down the outer aspect of the upper arm as a well-marked muscular elevation. Above the olecranon is the strap-like tendon of insertion of the triceps, which, when the elbow is fully flexed, forms an admirable posterior splint in supracondyloid fractures of the humerus.

The **brachial artery**, slightly overlapped in the upper half of the arm by the coraco-brachialis and in the lower half by the biceps, can be felt pulsating throughout the whole length of the anterior part of the internal bicipital furrow. The

course of the vessel may be mapped out upon the surface by drawing a line from the inner border of the coraco-brachialis, at the level of the posterior fold of the axilla, downwards to a point (opposite the neck of the radius) ½ in. below the middle of the bend of the elbow. In ligaturing the vessel, the edges of the coraco-brachialis and biceps muscles, together with the median nerve, furnish valuable guides to the artery, the mobility of which is often a source of trouble in performing the operation.

The **basilic vein**, which is superficial to the deep fascia in the lower third of the upper arm, is visible in the internal supracondyloid triangle and the lower part of the internal bicipital groove. The **cephalic vein** ascends a little internal to the outer edge of the triceps to reach the interval between the deltoid and pectoralis major.

The surface guide for the **median nerve** is the same as that for the brachial artery. The **ulnar nerve** is indicated superficially by a line extending from the outer wall of the axilla immediately behind the prominence of the coraco-brachialis, to the back of the internal condyle; in the upper half of the arm the nerve lies close behind the brachial artery under cover of the basilic vein, while in the lower half it lies a little behind the internal intermuscular septum, partially embedded in the fibres of the inner head of the triceps. To map out the course of the **musculo-spiral nerve**, first mark the point where it pierces the external intermuscular septum, viz. the junction of the upper and middle thirds of a line extending from the insertion of the deltoid to the external condyle; from this point draw a line obliquely downwards and forwards to the front of the external condyle, where the nerve divides into its radial and posterior interosseous branches. To map out the nerve as it lies in the musculo-spiral groove, draw a line from the same point obliquely upwards across the prominence formed by the outer head of the triceps to the junction of the posterior fold of the axilla with the upper arm. In fractures of the humerus in the neighbourhood of the insertion of the deltoid, the nerve is not infrequently lacerated, or so involved in the callus as to produce the condition known as "*drop-wrist*," the result of paralysis of the extensor muscles of the forearm. To cut down upon the nerve, commence the incision a little below the point where it pierces the external intermuscular septum, and carry it obliquely upwards and slightly backwards through the outer head of the triceps.

The **shaft** of the **humerus**, nowhere subcutaneous, is most readily manipulated in the region of the insertion of the deltoid, upwards along the outer head of the triceps, and downwards behind the external supracondyloid ridge. The **surgical neck**, situated between the tuberosities and the attachments of the muscles inserted into the region of the bicipital groove, is related to the outer wall of the axilla, and is on a level with the junction of the upper and middle thirds of the deltoid; at the same level are the circumflex vessels and nerves.

The shaft may be cut down upon with least injury to soft parts: (1) in its *upper third, anteriorly*, by an incision extending downwards through the anterior fibres of the deltoid, parallel, and a little external, to the bicipital groove; the sheath of the biceps will thus be avoided, and the small anterior circumflex artery will be the only vessel divided. (2) In the *upper third, posteriorly*, by an incision through the posterior fibres of the deltoid, the bone being reached just external to the origin of the outer head of the triceps, thus avoiding the musculo-spiral nerve; the circumflex vessels and nerves will be exposed at the upper part of the wound. (3) In the *lower third*, by an incision extending upwards from the back of the external condyle a little to the inner side of the external intermuscular septum.

## THE ELBOW.

In injuries about the elbow the diagnosis rests mainly upon the relative positions of the bony points, which are, therefore, of great importance. The **epicondylar processes** of the humerus are both subcutaneous and upon the same level, the internal being the more prominent. In the extended position of the elbow the tip of the **olecranon** is on a level with a line joining the epicondyles; when the forearm is flexed the olecranon descends, and when full flexion is

reached it lies 1 in. below the condyles, and in a plane anterior to the posterior surface of the lower end of the humerus. The **head** of the **radius**, which lies nearly 1 in. below the external epicondyle, is best manipulated from behind by placing the thumb upon it, while the semi-flexed forearm is being alternately pronated and supinated. Upon the outer part of the posterior aspect of the extended elbow is a distinct dimple, which overlies the **radio-humeral articulation**; this dimple, along with the hollows on either side of the olecranon, becomes effaced in synovial thickenings and effusions into the joint. The **coronoid process** is situated too deeply to be distinctly felt. The **lower epiphysis** of the humerus includes the articular portion of the lower extremity and the external condyle; it is, therefore, small and almost entirely intra-articular, so that foci of disease in its neighbourhood soon invade the cavity of the joint. The internal epicondyle ossifies as a

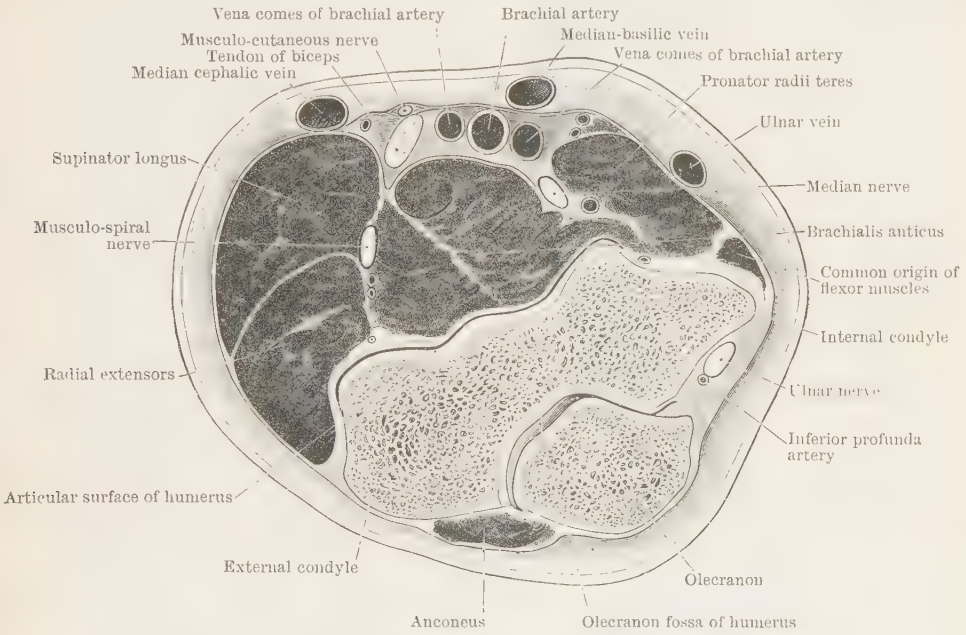

FIG. 926.—TRANSVERSE SECTION THROUGH THE BEND OF THE ELBOW.

separate epiphysis, which unites with the lower end of the diaphysis. In interpreting skiagrams of the elbow of children about six years of age and upwards, care must be taken not to mistake the centre of ossification in the radial portion of the lower epiphysis of the humerus for a fracture. In the commonest dislocation of the elbow, viz. with backward displacement of both bones of the forearm, the normal relative position of the bony points is lost, whereas in a transverse supra-condyloid fracture the normal relations are maintained. In the child the head of the radius is relatively smaller, and less firmly kept in position by the orbicular ligament than in the adult, so that it is liable to be partially dislocated, giving rise to the condition known as "*pulled elbow.*" To evacuate pus from the elbow-joint a vertical incision should be made over the dorsal aspect of the joint, immediately external to the olecranon.

The **median vein** is seen to bifurcate into median basilic and median cephalic ½ in. below the middle of the bend of the elbow; opposite the same point, but beneath the deep fascia, is the **bifurcation** of the **brachial artery**. The **median basilic** and **median cephalic** veins diverge as they ascend one on either side of the biceps tendon; the larger of the two veins, viz. the median basilic, is usually selected for the operations of venesection and transfusion. When the elbow is flexed the **biceps tendon** can be traced vertically through the centre of the bend of the elbow almost to its insertion. Passing downwards and inwards from the inner edge of the tendon is the **bicipital fascia**, which separates the median basilic vein from the brachial artery. If the finger nail be insinuated beneath the inner edge of the fascia the point of the

finger will rest upon, and feel the pulsations of, the brachial artery. The **median nerve** descends through the space a little internal to the brachial artery. The bifurcation of the **musculo-spiral nerve** takes place in front of the external condyle under cover of the supinator longus. The **ulnar nerve** can be rolled beneath the finger upon the back of the internal condyle; its position renders it liable to injury in severe fractures about the elbow, and in excising the joint care must be taken not to injure the nerve.

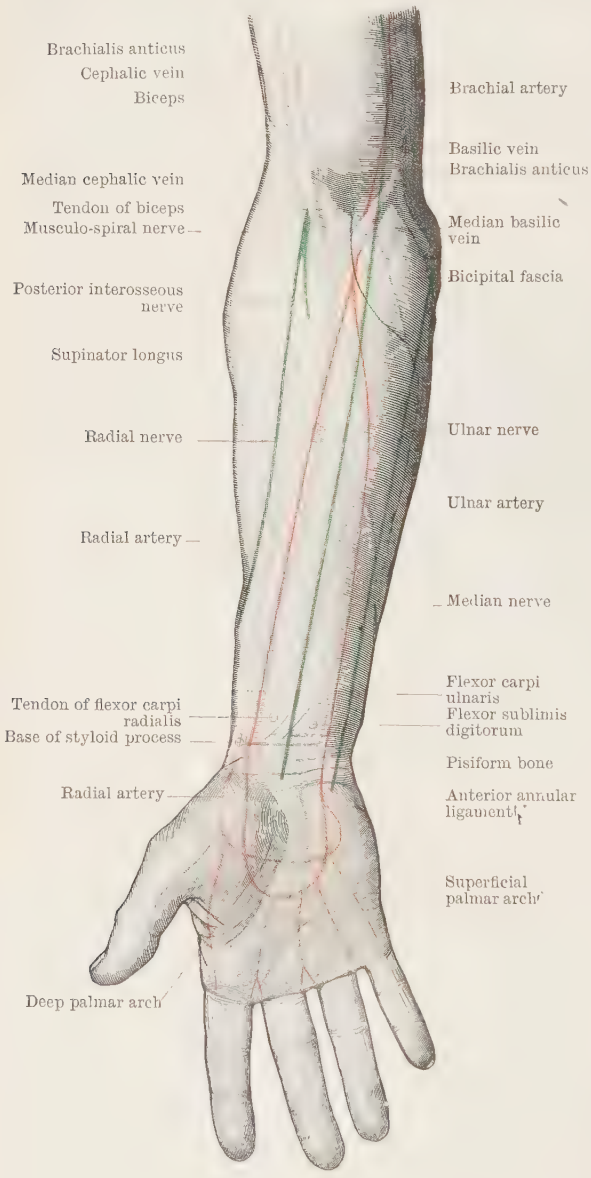

FIG. 927.—BEND OF ELBOW, FRONT OF FOREARM, AND PALM OF HAND.

## THE FOREARM AND HAND.

The upper half of the **radius** is deeply placed; the lower half is, however, easily palpated. The anterior border of its lower extremity is felt as a prominent transverse ridge, situated 1 in. above the thenar eminence; immediately below the ridge is the **radio-carpal articulation.** The **tip** of the **styloid process**, situated nearly $\frac{1}{2}$ in. lower than that of the ulna, is deeply placed at the outer side of the wrist, in the hollow between the extensor tendons of the first and second phalanges of the thumb. Upon the middle of the posterior surface of the lower end of the radius is the **dorsal radial tubercle** which intervenes between the extensor of the second phalanx of the thumb and the short radial extensor of the wrist; the tubercle can be distinctly felt, and may be taken as a guide to the upper end of Lister's dorso-radial incision for excision of the wrist. The posterior border of the ulna is subcutaneous throughout, and may be felt along the interval between the flexor and extensor carpi ulnaris muscles. Upon the ulnar side of the dorsal aspect of the wrist is a well-marked rounded prominence formed by the **lower extremity** of the **ulna**, anterior to which is the **styloid process**, the deep groove between the two being occupied by the tendon of the extensor carpi ulnaris.

The **carpal bones** are built up so as to form an arch, converted by the **anterior annular ligament** into a tunnel for the transmission of the flexor tendons. At each extremity of the arch the two bony points to which the ligament is attached furnish important landmarks. These bony points are: *externally*, the tubercle of the scaphoid and the ridge of the trapezium; *internally*, the pisiform and the hook of the unciform. The **tubercle** of the **scaphoid** is felt immediately above the root of the thenar eminence, midway between the tendons of the extensor ossis metacarpi

pollicis and the flexor carpi radialis; ½ in. below the tubercle of the scaphoid is the **ridge** of the **trapezium**, felt deeply beneath the inner part of the thenar eminence. At the root of the hypothenar eminence, and crossed by the crease which separates the forearm from the hand, is the **pisiform bone**, above which is the tendon of the flexor carpi ulnaris, passing to be inserted into it. The **hook** of the **unciform** is felt deeply beneath the radial side of the hypothenar eminence, and a full finger's breadth below and external to the pisiform.

FIG. 928.—PALM OF HAND.

The bases of the **first**, **third**, and **fifth metacarpals**, all of which can be readily identified on the dorsal aspect, furnish a sufficient guide to the line of the carpo-metacarpal articulations. At the base of the **third metacarpal** is a tubercle, which can be felt projecting from its dorsal aspect at a point 1¾ in. vertically below the tubercle upon the back of the lower end of the radius. This metacarpal tubercle marks the insertion of the extensor carpi radialis brevior, the favourite site for the development of a "*ganglion*," which may frequently be ruptured by pressing it firmly against the tubercle. Anteriorly, the carpo-metacarpal articulations correspond to the lower border of the anterior annular ligament.

The *prominences* of the *knuckles* are formed entirely by the heads of the metacarpal bones. Anteriorly, the **metacarpo-phalangeal articulations** are situated ¾ in. above the level of the web of the fingers; posteriorly, the joints may be felt

as a groove immediately above the projecting ridge at the base of the first phalanges. A well-marked crease crosses obliquely over the anterior aspect of the metacarpo-phalangeal joint of the thumb. To cut into the **first interphalangeal joints** from the front, incise along the *highest* of the creases in front of the joints; whereas to cut into the **terminal joints**, incise along the *lowest* of the creases in front of the joints. Posteriorly, the first and terminal interphalangeal articulations are opposite the distal of the various creases overlying the joints.

The most important *muscular* landmarks upon the front of the forearm are the supinator longus, the flexor carpi radialis and the pronator radii teres. The

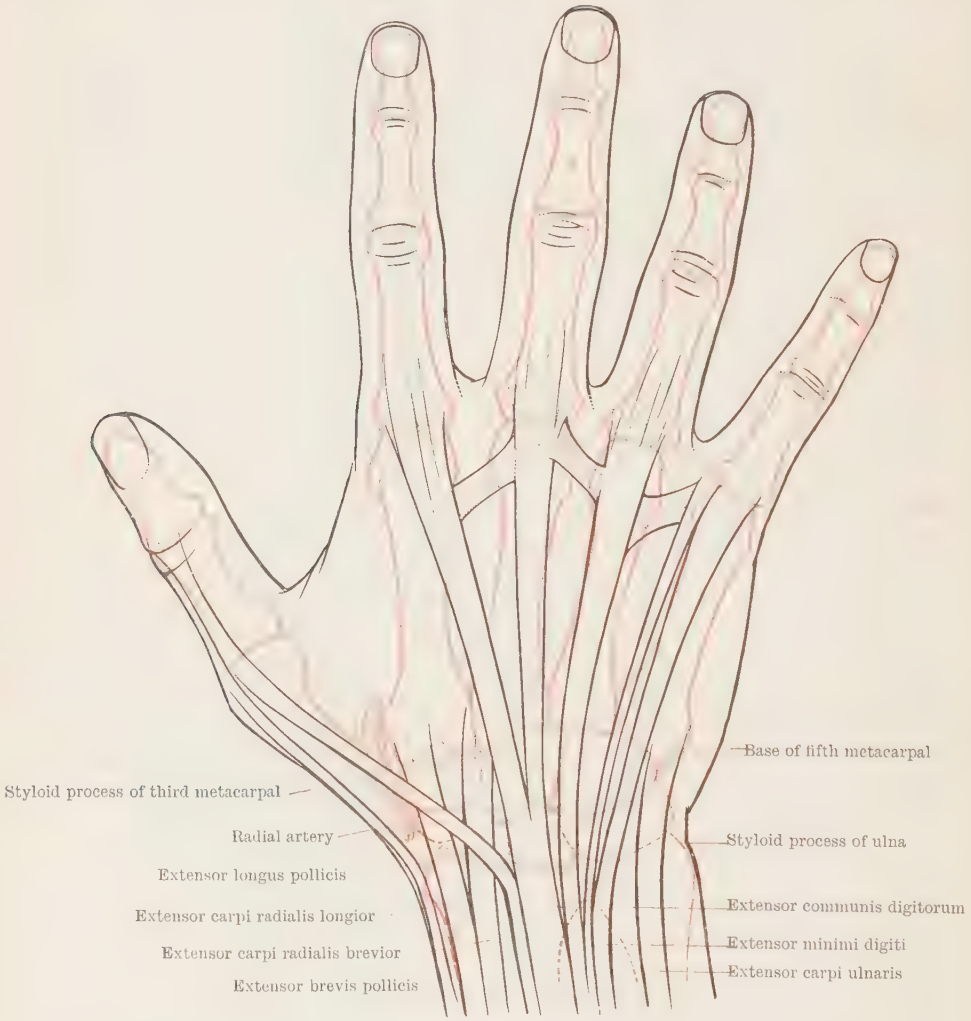

Fig. 929.—Dorsal Aspect of Hand.

**supinator longus** is thrown into prominence by flexing the semi-prone forearm against resistance. At the junction of the upper and middle thirds of the forearm the **pronator radii teres** passes beneath the supinator longus: between the two is the radial artery. The tendon of the **flexor carpi radialis** forms a prominent landmark descending along the middle of the anterior aspect of the forearm towards the ridge of the trapezium; the tendon of the **palmaris longus**, when present, is seen to its inner side.

At the back of the forearm the intermuscular septum between the radial and common extensors corresponds to the upper part of a line extending from the external epicondyle of the humerus to the tubercle on the back of the lower end of the radius. The **posterior interosseous nerve**, at the point at which it emerges from

the substance of the supinator brevis, will be found at the bottom of this septum, 2 in. below the head of the radius; below this point the septum is the best line along which to cut down upon the posterior surface of the radius. Winding across the lower third of this surface is an oblique prominence caused by the extensors of the metacarpal bone and first phalanx of the thumb.

The flexor sheaths of the palm and of the digits are of surgical importance in consequence of their liability to suppurative inflammation. The **common flexor sheath** begins $1\frac{1}{2}$ in. above the annular ligament, under which it extends to a little below the middle of the palm. The **digital flexor sheaths** extend from the bases of the terminal phalanges to the level of the distal transverse crease of the palm, opposite the necks of the metacarpal bones, *with the exception of the sheath of the little finger,* which is continuous with the common flexor sheath of the palm. The **sheath of the flexor longus pollicis** extends from the base of the terminal phalanx upwards to a point about 1 in. above the annular ligament; it frequently communicates with the common flexor sheath. From this anatomical arrangement it follows that suppuration in the sheaths of the little finger and thumb is specially liable to spread upwards into the palm, and thence underneath the annular ligament into the forearm.

The pulsations of the **radial artery** can readily be felt in the lower third of the forearm, midway between the outer border of the radius and the tendon of the flexor carpi radialis. The course of the vessel is indicated upon the surface by a line extending from the bifurcation of the brachial ($\frac{1}{2}$ in. below the middle of the bend of the elbow) to the tubercle of the scaphoid, around which, and below the tip of the styloid process, the artery winds to the back of the radial side of the wrist; in the latter situation the vessel, after passing beneath the extensor tendons of the thumb, dips into the palm through the proximal extremity of the first interosseous space. Incisions for opening or resecting the wrist are planned so as to avoid the vessel.

The upper third of the **ulnar artery** is deeply placed, and takes a curved course from the bifurcation of the brachial towards the inner part of the anterior surface of the forearm; the lower two-thirds of the vessel correspond to the lower two-thirds of a line drawn from the front of the internal condyle to the inner border of the pisiform bone. The course of the **ulnar nerve** corresponds to the whole of the above line.

The **median nerve** in the forearm may be mapped out by a line extending from a point midway between the centre of the bend of the elbow and the internal epicondyle, to a point midway between the styloid processes; in the lower third of the forearm the line follows the inner border of the tendon of the flexor carpi radialis. To evacuate pus spreading deeply up the front of the forearm, the incisions should be made on either side of the line corresponding to the median nerve. The **radial nerve** winds to the back of the forearm round the outer border of the radius beneath the tendon of the supinator longus, at the junction of the middle and lower thirds of the forearm. The summit, or most distal part of the **superficial palmar arch**, corresponds to the mid-point of a line extending from the middle of the lowest transverse crease of the wrist to the root of the middle finger; a line drawn from the outer border of the pisiform bone across the hook of the unciform, and thence in a curved direction downwards and outwards to this point, corresponds to the main or proximal part of the arch; the first and fourth digital branches overlie the fifth and third metacarpal bones respectively, while the second and third overlie the fourth and third interspaces respectively. The **deep arch** lies almost transversely, midway between the lower border of the anterior annular ligament and the superficial arch. The **radialis indicis** corresponds to the radial border of the index-finger.

The **ulnar nerve** and the commencement of its two divisions lie immediately to the inner side of the superficial palmar arch, so that the pisiform and the hook of the unciform are the guides to the nerve. The **median nerve** emerges from beneath the annular ligament opposite the inner edge of the thenar eminence, while the digital branches to the thumb follow its lower margin. Incisions for the removal of foreign bodies may therefore be made into the thenar with greater freedom than into the hypo-thenar eminence.

**Incisions to evacuate deep-seated pus in the palm** may be made in one or more of the following situations: (1) over the lower two-thirds of the second metacarpal bone; (2) over the distal half of the fourth metacarpal bone; (3) from the proximal part of the first incision an opening may be made through the first interosseous space on to the dorsum, care being taken to keep below the radial artery; (4) a longitudinal incision between the median and ulnar nerves, on the proximal side of the superficial palmar arch. At the wrist a longitudinal incision may be made immediately internal to the palmaris longus tendon, thus falling between the line of the median nerve and the ulnar artery. To open the **digital flexor sheaths**, incisions are made along the middle of the palmar surface of the fingers opposite the first and second phalanges. The **collateral digital vessels** and **nerves** descend along the lateral aspects of the fingers, nearer the flexor than the extensor surfaces. In cutting down upon the dorsal aspects of the phalanges, the incisions should be made to one or other side of the extensor tendon, preferably upon the ulnar side, to avoid division of the insertions of lumbrical muscles. The subcutaneous tissue of the palmar aspect of the terminal phalanges is connected by fibrous processes with the periosteum; hence the frequency of necrosis of the terminal phalanx in suppurative inflammations in this region.

## THE LOWER EXTREMITY.

### THE BUTTOCK.

The region of the hip or buttock extends from the crest of the ilium above to the gluteal fold below. The highest point of the **iliac crest**, situated a little behind its middle, is on a level with the fourth lumbar spine; the **anterior superior spine** of the **ilium** is directed forwards, and belongs to the groin, which it limits externally; the **posterior superior spine**, situated at the bottom of a dimple or small depression, is on a level with the second sacral spine, and corresponds, therefore, to the middle of the **sacro-iliac joint**. Two and a half inches behind the anterior superior spine is a prominence upon the outer lip of the iliac crest; this prominence, which is termed the **tubercular point**, is the most external part of the crest, and have been referred to in dealing with the surface anatomy of the abdomen. A hand's breadth below the tubercle of the crest is the **great trochanter** of the femur, the most external bony landmark of the hip; its anterior and posterior borders are best felt between the fingers and thumb, while the limb is slightly abducted to relax the ilio-tibial band, and if the thigh be now rotated, it will be noted that the trochanter rotates around the segment of a circle, the radius of which is formed by the head and neck of the femur; in non-impacted fractures of the neck of the femur the trochanter rotates around the segment of a much smaller circle. *Nelaton's line*, drawn from the anterior superior spine to the most prominent part of the ischial tuberosity, crosses the hip at the level of the upper border of the great trochanter; this line is employed to ascertain the presence or absence of upward displacement of the trochanter. Chiene demonstrates the relative height of the trochanters by stretching two tapes across the front of the pelvis, one between the anterior superior spines, and the other between the upper borders of the trochanters; the lower tape will converge towards the upper on the side of the upward displacement. A line prolonging the anterior border of the great trochanter vertically upwards touches the iliac crest at the tubercular point. The **ischial tuberosity**, in the erect posture, is overlapped by the lower border of the gluteus maximus; its most prominent part is felt a little above the inner part of the gluteal fold. If the hip be rotated inwards, the **lesser trochanter** of the femur may be felt by deep palpation above the outer end of the gluteal fold; it corresponds to the interval between the lower border of the quadratus femoris and the upper border of the adductor magnus, and therefore, also, to the level of the internal circumflex artery.

The **lower border** of the **gluteus maximus** lies a little above the **gluteal fold** internally, crosses it about its middle, and is continued downwards and outwards to meet the upper end of the furrow of the external intermuscular septum, at the junction of the upper and middle thirds of the femur. The inner borders of the two great gluteal muscles are separated by the deep **gluteal cleft**, which extends upwards and backwards from the perineum to the level of the fourth sacral spine,

where it opens out into the triangle upon the back of the sacrum. Anteriorly the buttock is limited by the prominence of the **tensor fasciæ femoris muscle**, which extends downwards and somewhat backwards from the anterior end of the crest, to join the ilio-tibial band below the root of the great trochanter.

The **gluteal artery** reaches the buttock immediately below the upper border of the great sacro-sciatic foramen, opposite a point corresponding to the junction of the upper and middle thirds of a line drawn from the posterior superior iliac spine to the upper border of the great trochanter. To expose the vessel, the incision should be made along this line, which has the advantage of running parallel to the fibres of the gluteus maximus, as well as parallel to the interval between the gluteus medius and pyriformis muscles.

The **great sciatic nerve** enters the buttock at a point corresponding to the junction of the upper and middle thirds of a line drawn from the posterior superior iliac spine to the ischial tuberosity; from this point the nerve passes downwards and slightly outwards upon the ischium to a point midway between its tuberosity and the great trochanter. The **spine of the ischium** and the **pudic vessels** are situated opposite the junction of the lower and middle thirds of the above line. The vessels and nerves which enter the buttock through the great sacro-sciatic foramen *below the pyriformis*, may be exposed through an incision below and parallel to that above described for exposing the gluteal artery, viz. an incision corresponding to the middle two-fourths of a line extending from the upper end of the gluteal cleft to the root of the great trochanter; the deep landmarks are the lower border of the pyriformis and the root of the ischial spine.

## THE BACK OF THE THIGH.

The **hamstring muscles**, and especially the tendon of the biceps and semi-

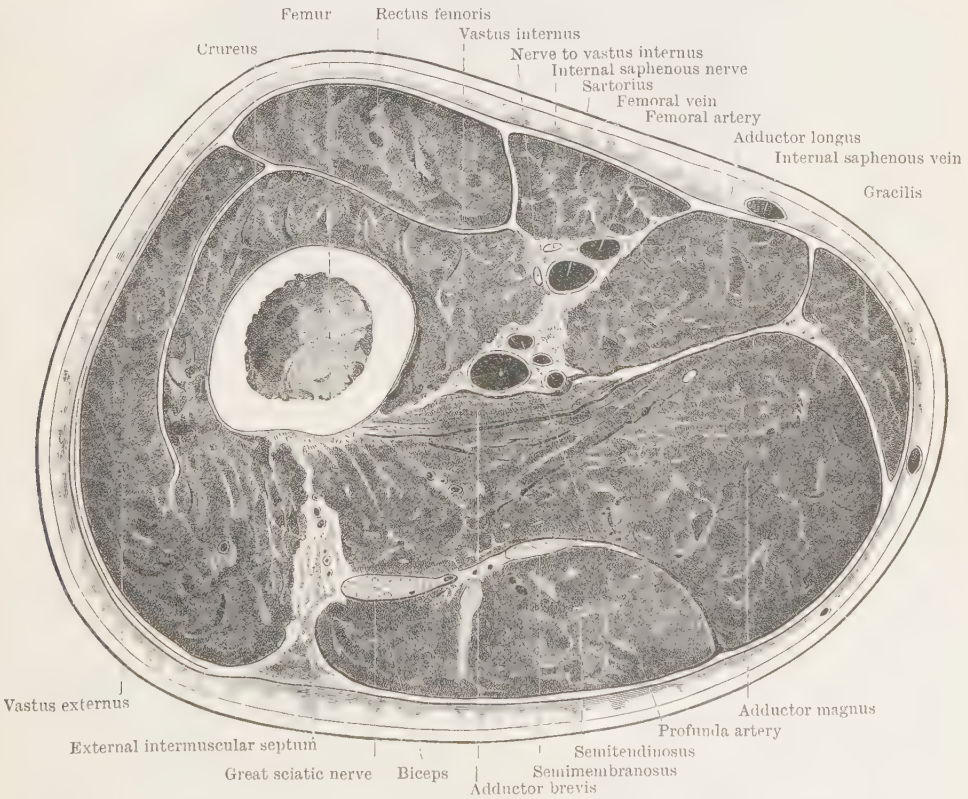

FIG. 930.—SECTION THROUGH THIGH AT THE LEVEL OF THE UPPER PART OF HUNTER'S CANAL.

tendinosus are thrown into prominence either by standing on tiptoes with the

knees slightly flexed, or by flexing the leg against resistance. By throwing the hamstrings into action, the line of the **external intermuscular septum** of the thigh is indicated by a well-marked furrow, extending from the lower edge of the insertion of the gluteus maximus to the outer aspect of the knee; behind this furrow is the **biceps**, and in front of it is the large **vastus externus**, covered by the strong ilio-tibial portion of the fascia lata. The **shaft of the femur** may be cut down upon along the whole length of this furrow with least injury to the soft parts; the trigone of the femur and deep-seated popliteal abscesses are most conveniently reached through the lower part of the same incision. The course of the **great sciatic nerve** corresponds to the upper half of a line extending from a point midway between the tuberosity of the ischium and the great trochanter to the centre of the popliteal space. The nerve enters the thigh under cover of the outer border of the biceps, whereas the **small sciatic**, which takes the same line, descends superficial to the

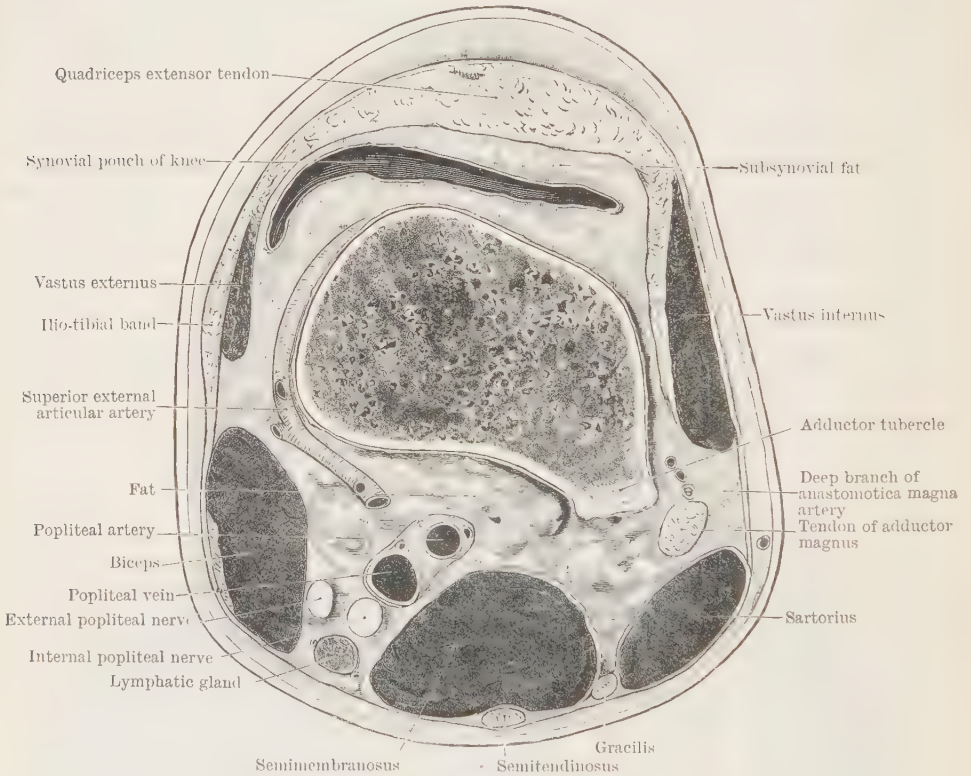

FIG. 931.—SECTION THROUGH THE THIGH IMMEDIATELY ABOVE THE PATELLA.

biceps, between it and the fascia lata. In the operation of stretching the great sciatic the nerve is cut down upon immediately below the lower border of the gluteus maximus. The surgeon, standing on the side of the patient opposite to the leg to be operated upon (Chiene), makes an incision in the line of the nerve through the integuments and fascia lata, and, sweeping the index-finger round the outer border of the biceps, hooks up the nerve as it lies between that muscle and the adductor magnus. The **external popliteal nerve** may be rolled under the finger as it descends immediately behind the tendon of the biceps and the head of the fibula; so close is the nerve to the tendon that the latter should be divided, in cases where this is necessary, by the open method rather than subcutaneously.

Abscesses may reach the flexor compartment of the thigh from various sources, viz.: (1) from the posterior aspect of the hip-joint: (2) from the pelvis through the great sacro-sciatic foramen; (3) from one or other of the bursæ under the gluteus maximus; (4) from the front of the hip-joint by passing backwards under the tensor fasciæ femoris; or by winding backwards beneath the neck of the femur, and through the interval between the quadratus femoris and the adductor magnus; (5) from the iliac fossa under Poupart's ligament into Scarpa's triangle, and thence to the back of

the thigh by one or other of the routes already mentioned; (6) the pus may spread upwards from the trigone of the femur, the knee, a popliteal gland, or from a bursa.

## THE POPLITEAL SPACE.

When the knee is extended the **popliteal fascia** is put upon the stretch, and obliterates the hollow of the popliteal space; by flexing the knee the fascia is relaxed, and the fingers may be pressed deeply into the upper or femoral division of the space; as a rule, the pulsations of the popliteal artery can be felt. Beneath the **semitendinosus** is the fleshy **semimembranosus**, which bulges into the space and overlaps the upper part of the popliteal artery. Between the semimembranosus and the inner head of the gastrocnemius is the most important **bursa** in the popliteal region; it not infrequently becomes distended with fluid, and then presents usually

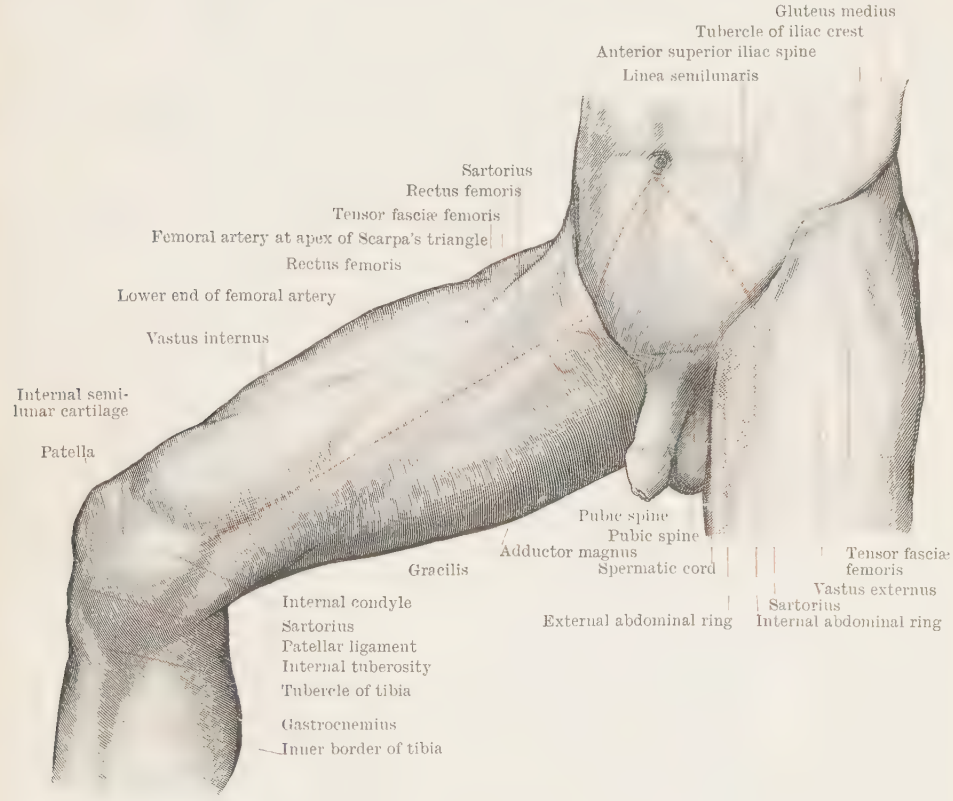

FIG. 932.—THE THIGH AND GROIN.

a more or less sausage-shaped outline; according to Holden, the bursa communicates with the cavity of the knee-joint in one subject out of five.

To map out the line of the **popliteal vessels** and the **internal popliteal nerve**, draw a line from a point a little internal to the upper angle of the space to a point midway between the condyles of the femur, and thence down the middle of the space to the level of the lower part of the tubercle of the tibia. The internal popliteal nerve lies immediately beneath the deep fascia; the artery is separated from the trigone of the femur by a quantity of fat. The popliteal **lymphatic glands** lie beneath the popliteal fascia, one upon the internal popliteal nerve, the others deeply in the space (Leaf).

## THE FRONT OF THE THIGH.

Between the front of the thigh and the abdomen is the *fold of the groin*, at the bottom of which **Poupart's ligament** can be felt as a tense band, stretching from the anterior superior spine of the ilium to the spine of the pubis. The **anterior superior**

**spine** looks directly forwards; comparative measurements of the lower extremities are made by stretching a tape from it to the tip of one or other of the malleoli, care being taken that the pelvis is horizontal, and the limbs in corresponding positions. The **pubic spine** is felt under the upper and outer part of the mons Veneris and at a corresponding point in the male; between the spine and the symphysis is the **crest** of the pubis, the two crests together forming a rounded subcutaneous bony ridge. A line extending from the pubic spine horizontally outwards across the front of the thigh crosses the front of the hip-joint at the level of the lower part of the head of the femur. The cord-like **tendon** of the **adductor longus** is readily felt, and a point about 1 in. below the pubic spine is selected for performing the operation of subcutaneous tenotomy of the tendon.

The centre of the **saphenous opening** is situated 1½ in. below and external to the pubic spine; it overlies the inner (hernial) and middle (venous) compartments of the femoral sheath; behind the outer border of the opening is the arterial compartment of the sheath; crossing over the lower border is the termination of the long saphenous vein. A femoral hernia makes its way into the thigh beneath the upper edge of the opening. The course of the **long saphenous vein** in the thigh is indicated by a line extending from the adductor tubercle of the internal condyle of the femur to the lower part of the saphenous opening.

The **horizontal** or **inguinal chain** of **lymphatic glands** can usually be felt along, and a little below, the line of Poupart's ligament; when the glands are inflamed the surgeon should not neglect to examine the buttocks and anus as well as the external genitals. The **vertical** or **femoral chain** lies in close relation to the upper end of the long saphenous vein. Deeper glands also are met with beneath the cribriform fascia, close to the inner side of the femoral vein, and there is generally one in the crural canal. To clear out the glands in the groin an incision should be made parallel to, and a finger's breadth below, the whole length of Poupart's ligament.

To map out the course of the **femoral artery**, the thigh being slightly flexed and rotated outwards, draw a line from the mid-point between the anterior superior iliac spine and the symphysis pubis to the adductor tubercle at the upper and back part of the internal condyle; rather less than the upper third of this line corresponds to the femoral artery in Scarpa's triangle, while rather more than its middle third corresponds to the artery as it lies in Hunter's canal. The seat of election for ligature of the vessel is at the apex of Scarpa's triangle. To compress the common femoral, pressure should be made directly backwards against the pubic eminence, and not against the head of the femur; to compress the femoral in Hunter's canal, pressure should be made outwards against the inner surface of the shaft of the femur.

On the outer aspect of the thigh the **fascia lata** is thick, aponeurotic, and loosely attached to the vastus externus; hence the tendency of abscesses to travel downwards beneath it towards the knee. The **sartorius**, which forms the most important muscular landmark of the thigh, may be thrown into prominence by maintaining the thigh unsupported, flexed, and slightly rotated outwards. Observe that in the upper third of the thigh it forms the outer boundary of Scarpa's triangle; in the middle third it is placed over Hunter's canal; while in the lower third it lies in front of the inner hamstrings. External and adjacent to the upper part of the sartorius is the prominence of the **tensor fasciæ femoris**, which, as it descends, diverges from the sartorius; in the angle between the two the tendon of the rectus may be felt as it overlies the lower part of the anterior aspect of the capsule of the hip-joint.

The inner aspect of the lower half of the **shaft of the femur** may be conveniently cut down upon through the vastus internus, where it comes to the surface between the sartorius and rectus muscles; the incision should be made in the direction of a line extending from a point midway between the inner border of the patella and the adductor tubercle, to the anterior superior iliac spine.

The front of the **hip-joint** may be reached through an incision downwards from the anterior superior iliac spine, either along the inner or the outer border of the sartorius; in the former case the deeper part of the dissection passes between the iliacus and the inner border of the rectus, while in the latter case the joint is reached external to the rectus tendon, between it and the

anterior borders of the gluteus medius and minimus muscles. The ascending branch of the **external circumflex artery** crosses the capsule parallel to, and immediately above, the anterior intertrochanteric line. The **ilio-psoas** crosses the anterior and the inner part of the capsule; between the two is a **bursa**, which frequently communicates with the joint through the thin part of the capsule internal to the ilio-femoral band; it is by way of this communication that a psoas abscess occasionally gives rise to secondary tubercular disease of the hip-joint. One of the commonest situations to meet with an abscess in hip-joint disease is in the cellular tissue and fat under the tensor fasciæ femoris; or the pus may pass below and to the inner side of the neck of the femur, and thence along the course of the internal circumflex artery to the back of the thigh. *To tap or explore the hip-joint*, the puncture should be made in the interval between the sartorius and the tensor fasciæ femoris, 2 to 3 in. below the anterior superior iliac spine; if the instrument is then pushed upwards, inwards, and backwards beneath the tendon of the rectus, it will pass through the capsule a little above the anterior intertrochanteric line. Regarded from the point of view of **dislocation**, the regions of the cotyloid notch and of the inferior part of the capsule are the weak points in the joint; it follows, therefore, that abduction favours dislocation by bringing the head of the femur into relation with these two weak areas.

## THE KNEE.

With the knee extended and the quadriceps relaxed, the **patella** can be readily outlined and moved from side to side upon the femoral condyles. On contracting the quadriceps its tendon springs forwards and is felt as a tense band above the patella; while the **patellar ligament**, which has become tense and prominent, may be traced to the lower part of the tubercle of the tibia. In front of the lower part of the patella and of the upper part of the patellar ligament is the **pre-patellar bursa**, into which effusion takes place in the condition known as housemaid's knee. Beneath and on either side of the patellar ligament is a well-circumscribed pad of fat, palpation of which gives rise to a feeling closely resembling true fluctuation. In extension, only the lower pair of articular facets of the patella are in contact with the trochlear surface of the femur. In semiflexion the middle pair of facets rests upon the trochlea; in this position the inner margin of the internal condyle, the upper border of the inner tuberosity of the tibia, and the lower part of the patella are all distinctly visible, and together bound a triangular depression, which overlies the line of the joint and contains the anterior part of the **internal semilunar cartilage**; it is in this triangle that the surgeon searches for a displaced or thickened internal semilunar cartilage, for a loose body, and for "lipping" of the edge of the articular cartilage in chronic osteo-arthritis. A similar, but less well defined, triangle may be felt immediately external to the lower edge of the patella. When the quadriceps is thrown into

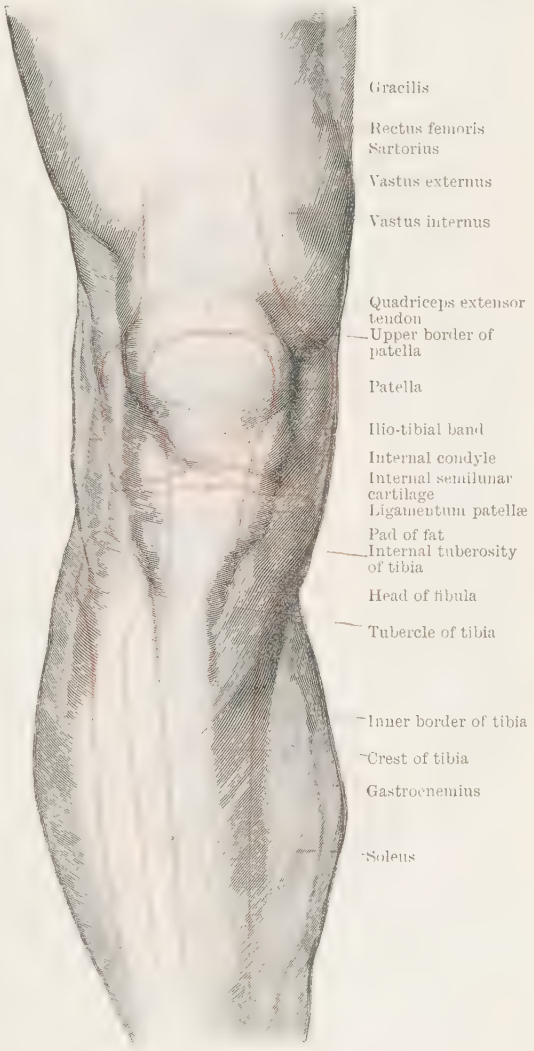

FIG. 933.—ANTERIOR ASPECT OF KNEE.

sudden or violent contraction, as in preventing oneself from falling backwards, the patella may be transversely fractured at the moment of partial flexion. In full flexion almost the whole of the trochlear surface of the condyles is exposed to palpation, covered, however, by the stretched quadriceps tendon.

The upper part of the inner surface of the internal condyle is overlapped by the muscular prominence of the lower fibres of the **vastus internus**. Leading upwards from the internal condyle is a slight furrow, corresponding to the interval between the lower part of the vastus internus and the sartorius; at the bottom of the furrow the cord-like **tendon of the adductor magnus** may readily be felt, and followed down to its insertion into the **adductor tubercle**; the latter, situated at the junction of the internal supracondyloid ridge with the upper and back part of the internal condyle, marks the level of the **epiphysial cartilage**. Anteriorly and posteriorly the epiphysial cartilage lies immediately above the highest part of the articular cartilage.

Disease of the lower end of the diaphysis of the femur generally invades the trigone of the femur and the popliteal space rather than the cavity of the knee-joint. In *Macewen's operation for knock-knee*, the incision (through which the osteotome is introduced to divide the femur) is carried down to the bone through the vastus internus a little above the internal condyle, a finger's breadth above the summit of the trochlea, to avoid injury to the epiphysial cartilage, and the same distance in front of the adductor tendon, to avoid injury to the deep branch of the anastomotic artery.

Below the internal condyle is the subcutaneous **inner tuberosity of the tibia** across which the tendons of the sartorius, gracilis, and semitendinosus pass to their insertion. Between the above tendons and the inner head of the gastrocnemius is a groove which winds downwards and forwards from the popliteal space; an incision along this groove will expose the **long saphenous vein** and **nerve** and the superficial branch of the anastomotic artery.

On the outer side of the knee is the **ilio-tibial band**, which, after crossing and obscuring the line of the joint, is attached to the **outer tuberosity of the tibia**. By semiflexion of the knee the posterior border of the band is thrown into relief, and a well-marked furrow intervenes between it and the prominent tendon of the biceps; the lower part of the shaft of the femur and the trigone may be reached through an incision along this furrow. Under cover of the ilio-tibial band, as it crosses the line of the joint, are the **external semilunar cartilage**, the **inferior external articular artery**, and the **external lateral ligament**. The **head of the fibula**, with the **tendon of the biceps** passing to be inserted into it, are rendered distinctly visible by semiflexing the knee; the former lies on a level with the tubercle of the tibia, 1½ in. behind and a little below the most prominent part of the outer tuberosity of the tibia. Immediately below the head of the fibula is the termination of the **external popliteal nerve**, which is liable to be contused from blows, and in fractures of the neck of the fibula.

The **synovial membrane** of the knee-joint extends downwards anteriorly as far as the level of the upper border of the tibia; posteriorly, it dips downwards for a short distance behind the popliteal notch of the tibia, to form a small cul-de-sac, the close relation of which to the popliteal artery must be borne in mind in performing the operation of excision of the knee. Anteriorly, the synovial cavity extends upwards beneath the quadriceps in the form of a pouch, which reaches nearly two inches above the articular surface of the femur; posteriorly, there is no extension of the synovial cavity upwards above the condyles; laterally, the synovial membrane covers the anterior third of the outer surface of each condyle.

In **effusion into the knee-joint** the hollows become obliterated, the patella is floated up, and fluctuation may be obtained above, below, and to either side of the patella.

To pass a tube through the knee-joint for drainage, two short vertical incisions should be made—one on each side of the joint at the level of the upper part of the patella, and a finger's breadth behind its lateral edges. In **arthrectomy** of the knee for tubercular disease, the subsynovial fat facilitates the separation of the suprapatellar pouch from the lower and anterior part of the shaft of the femur; to expose the **pouches behind the condyles**, the crucial ligaments must be divided.

## THE LEG.

The inner surface of the **tibia** is subcutaneous throughout, hence the seat of a fracture of the shaft is, as a rule, easily felt, and the lower extremity of the upper

fragment is liable to perforate the skin. The skin over the lower half of this surface is the commonest seat of varicose and callous ulcers, which are frequently prevented from healing by adhesion of the floor of the ulcer to the periosteum.

The **shaft of the fibula**, situated on a plane posterior to that of the tibia, is, with the exception of the triangular subcutaneous surface above the external malleolus, deeply placed amongst the muscles. To examine the fibula, the surgeon should stand on the opposite side of the patient and manipulate the bone along the line of the intermuscular septum between the peronei and the muscles of the calf.

The greater fulness of the antero-external surface of the leg, as compared with its inner surface, is due to the presence of the **extensor** and **peroneal groups of muscles**. When these groups are thrown into action, the individual muscles are mapped out upon the surface by the grooves corresponding to their intermuscular septa. The **posterior peroneal septum** is seen as a well-marked furrow, extending from the posterior aspect of the head of the fibula to the hollow behind the external malleolus; in front of it are the **peronei muscles**, the *longus* giving rise to a prominence on the upper half of the leg, while the *brevis* is prominent on the lower half; behind the septum is a prominence formed by the outer border of the **soleus**, which projects beyond that of the **gastrocnemius**.

FIG. 934.—OUTER ASPECT OF KNEE AND LEG.

It is along the line of the posterior peroneal intermuscular septum that incisions should be made to expose the fibula; to avoid the musculo-cutaneous nerve, however, the incision must not extend higher than 1 in. below the head of the fibula.

The furrow between the extensors and the two peronei, the **anterior peroneal septum**, is much less distinct, and runs in a line from the anterior border of the head of the fibula to the anterior border of the external malleolus; the **cutaneous portion of the musculo-cutaneous** nerve corresponds to the lower half of this line. At the junction of the middle and lower thirds of the leg the extensor muscles incline inwards over the anterior surface of the tibia.

The **anterior tibial artery** reaches the front of the interosseous membrane 2 in. below the tubercle of the tibia; in the upper two-thirds of its course it lies upon the

interosseous membrane, while in its lower third it winds on to the front of the tibia, to terminate at a point opposite the ankle-joint, midway between the two malleoli. *Incisions to expose the vessel* should strike the outer border of the tibialis anticus, which corresponds to a line drawn from a point midway between the external tuberosity of the tibia and the head of the fibula, to the termination of the vessel.

When the muscles of the calf are thrown into action, a groove is seen between the two heads of the **gastrocnemius**, the fleshy fibres of which extend a little below the middle of the leg. The fleshy fibres of the **soleus** extend to the junction of the middle and lower thirds of the leg, and project beyond the margins of the gastrocnemius. The narrowest part of the **tendo Achillis** is situated opposite the bases of the malleoli, and it is here that the tendon is divided in the operation of tenotomy. The **short saphenous vein**, which lies a little to the outer side of the tendon, gradually reaches the middle of the calf, along which it ascends to the middle of the popliteal space. The **internal saphenous vein** and **nerve** lie along the inner border of the tibia.

The course of the **posterior tibial artery** is mapped out by drawing a line from the lower angle of the popliteal space, at the level of the lower border of the tubercle of the tibia, to a point midway between the internal malleolus and the tendo Achillis. *To expose the vessel* in the upper half of the leg, an incision is made parallel to and $\frac{1}{2}$ in. behind the inner border of the tibia; after retracting the inner border of the gastrocnemius and dividing the tibial origin of the soleus, the artery is found lying on the tibialis posticus. In exposing the artery below the soleus, divide two layers of deep fascia and keep the knife directed towards the tibia.

The **peroneal artery** is given off 3 in. below the head of the fibula; incisions to expose the vessel are made in the direction of a line extending from the posterior border of the head of the fibula to a point midway between the external malleolus and the tendo Achillis.

## THE FOOT AND ANKLE.

The tip of the **external malleolus** is situated $\frac{1}{4}$ in. lower and $\frac{3}{4}$ in. further back than that of the **internal malleolus**. Above the external malleolus is the

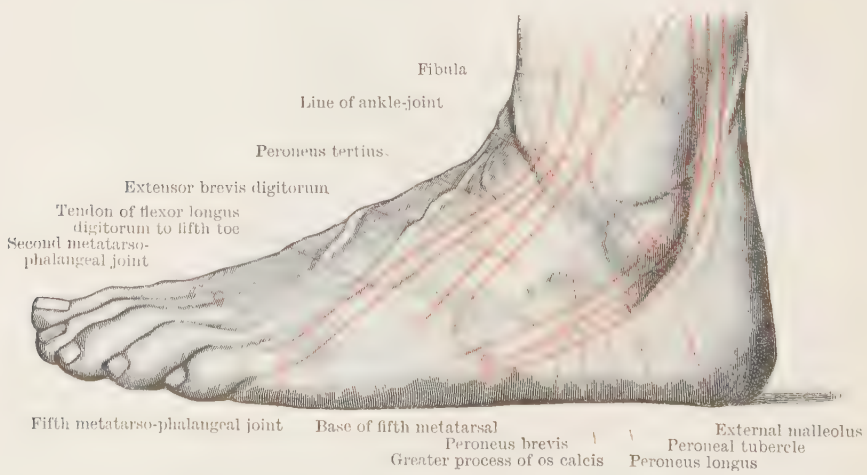

Fig. 935.—Outer Aspect of Foot and Ankle.

triangular subcutaneous surface of the fibula, the apex of which corresponds to the lower end of the extensor-peroneal intermuscular septum.

The **line of the ankle-joint** can be felt on either side of the extensor tendons, and when the foot is extended the anterior part of the superior articular surface of the **astragalus** forms a visible prominence below the anterior border of the lower end of the tibia. The small posterior surface of the astragalus is felt below and behind

the internal malleolus, at the anterior part of the hollow between it and the heel. In *effusions into the ankle-joint* the hollows in front and behind the malleoli are obliterated, and the extensor tendons are raised from the front of the joint.

A finger's breadth below the tip of the internal malleolus is the **sustentaculum tali**; $1\frac{1}{4}$ in. in front of the latter, and midway between the dorsal and plantar margins of the inner aspect of the foot, is the **tubercle of the scaphoid** (the inner landmark in Chopart's amputation), which is generally visible, and always distinctly palpable. The **calcaneo-astragaloid joint** lies immediately below the sustentaculum, while close above it the **tendon of the tibialis posticus** may be rendered visible, as it extends from behind the tip of the internal malleolus to the tubercle of the scaphoid. An inch and a half in front of the tubercle of the scaphoid is the **joint between the internal cuneiform and the first metatarsal**; the ridge at the base of the latter bone furnishes a good guide to the articulation. The first **metatarso-phalangeal joint** lies a little in front of the middle of the ball of the great toe.

A finger's breadth vertically below the tip of the external malleolus is the **peroneal tubercle** of the os calcis, and midway between the two is the **calcaneo-astragaloid joint**; the tubercle is, when present, a trustworthy guide to the level at which the **two peronei tendons** cross the outer surface of the os calcis. The **greater process** of the **os calcis** is felt in the triangular interval between the tendons of the

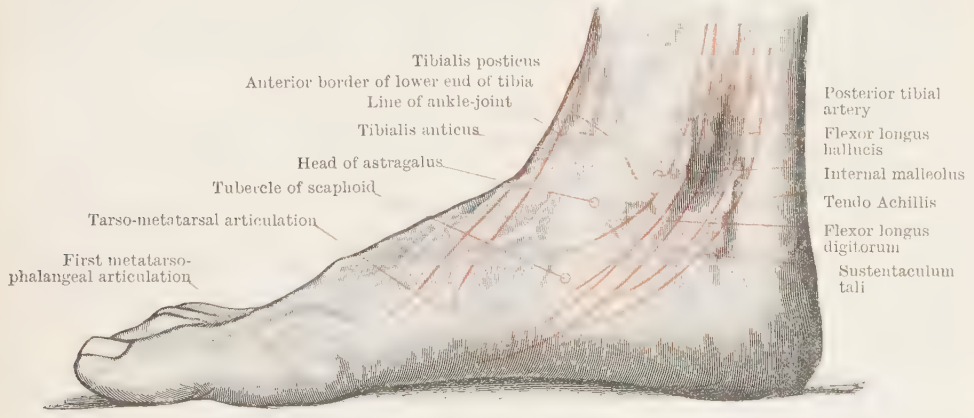

FIG. 936.—INNER ASPECT OF FOOT AND ANKLE.

peroneus brevis and tertius; the **calcaneo-cuboid joint**—the outer landmark in Chopart's amputation—is placed a little in front of the mid-point between the tip of the external malleolus and the base of the fifth metatarsal bone. To open the **outer tarso-metatarsal articulations**, the knife, entered behind the projecting base of the fifth metatarsal bone, should be directed forwards as well as inwards. On the dorsum of the foot the tarsal joints are obscured by the extensor tendons. The **synovial membrane** of the **ankle-joint** is prolonged on to the neck of the astragalus, and care must be taken to avoid opening the ankle-joint in performing Chopart's amputation.

The **line** of the **tarso-metatarsal joints** extends nearly 1 in. further forwards on the inner than on the outer border of the foot; between these points the joint-line takes a zigzag course on account of the second metatarsal bone extending backwards between the internal and external cuneiform bones. The joint between the second metatarsal and middle cuneiform is nearly $\frac{1}{2}$ in. behind that between the first metatarsal and internal cuneiform, and nearly $\frac{1}{4}$ in. behind that between the third metatarsal and the external cuneiform. The strong transverse inter-osseous ligament (*Lisfranc's ligament*), which connects the outer surface of the internal cuneiform with the base of the second metatarsal, must be divided in the tarso-metatarsal amputation of Lisfranc. In order to preserve the insertions of the two tibial and the three peroneal muscles it is advisable, when possible, instead of disarticulating at "Lisfranc's joint," to saw through the metatarsal bones just in front of their bases.

The **metatarso-phalangeal articulations** are situated 1 in. behind the web of the toes. In disarticulating a toe, the transverse metatarsal ligament, which unites the heads of the metatarsal bones, should not be injured.

The **tendon** of the **tibialis posticus** may be felt, and, by inverting the foot, seen, as it extends from behind the tip of the internal malleolus to the tubercle of the scaphoid; it crosses the astragalus immediately above the sustentaculum tali.

In the commonest form of club-foot, viz. *talipes equino-varus*, the tubercle of the scaphoid is approximated to the internal malleolus, so that tenotomy of the tendon should be performed through a puncture a little below the tip of the internal malleolus; if the knife, after dividing the tendon, be carried down to the bone, the **inferior calcaneo-scaphoid ligament** will be divided and the **astragalo-scaphoid joint** opened, a procedure which is called for before the foot can be brought into good position.

Crossing the front of the ankle-joint, from within outwards, are the following tendons: viz. the **tibialis anticus**, the largest and most prominent; the **extensor longus hallucis**, the **extensor longus digitorum**, and the **peroneus tertius**. The **extensor brevis digitorum** gives rise to a fleshy pad which overlies the dorsal aspect of the calcaneo-cuboid joint. When the foot is everted, the tendon of the **peroneus brevis** may be seen extending from the tip of the external malleolus to the base of the fifth metatarsal bone; immediately below it is the tendon of the **peroneus longus**, which, as it winds round the cuboid, is obscured by the fleshy fibres of the abductor minimi digiti muscle. The **abductor hallucis muscle**, although described along with the sole, forms a fleshy pad along the inner border of the foot below the sustentaculum tali.

An incision, extending from the tubercle of the scaphoid to the middle of the inner border of the heel, will expose the various tendons, vessels, and nerves, as they pass from the inner ankle into the sole beneath the abductor hallucis.

The **dorsalis pedis artery** may be mapped out on the surface by drawing a line from a point opposite the ankle-joint, midway between the tips of the two malleoli, to the hinder end of the first interosseous space; the vessel may be compressed against the inner column of the tarsal bones. The **internal saphenous vein** and **nerve** lie between the anterior border of the internal malleolus and the tendon of the tibialis anticus; the **external saphenous vein** and **nerve** take the same course as the tendon of the peroneus brevis.

The **internal plantar vessels** and **nerves** lie along the **internal intermuscular septum**, which corresponds to a line drawn from the under surface of the inner tuberosity of the os calcis to the interval between the first and second toes. The **external plantar vessels** and **nerves** may be exposed by an incision along the **external intermuscular septum**, which runs in a line extending from the middle of the under surface of the heel to the fourth toe (Kocher); to map out the course of the **plantar arch**, draw a line across the sole from the inner side of the base of the fifth metatarsal bone to the hinder end of the first interosseous space.
